1. Introduction

The LISFLOOD model is a hydrological rainfall-runoff model that is capable of simulating the hydrological processes that occur in a catchment. LISFLOOD has been developed by the floods group of the Natural Hazards Project of the Joint Research Centre (JRC) of the European Commission. The specific development objective was to produce a tool that can be used in large and trans-national catchments for a variety of applications, including:

- Flood forecasting
- Assessing the effects of river regulation measures
- Assessing the effects of land-use change
- Assessing the effects of climate change

Although a wide variety of existing hydrological models are available that are suitable for each of these individual tasks, few single models are capable of doing all these jobs. Besides this, our objective requires a model that is spatially distributed and – at least to a certain extent - physically-based. Also, the focus of our work is on European catchments. Since several databases exist that contain pan-European information on soils (King et al., 1997; Wösten et al., 1999), land cover (CEC, 1993), topography (Hiederer & de Roo, 2003) and meteorology (Rijks et al., 1998), it would be advantageous to have a model that makes the best possible use of these data. Finally, the wide scope of our objective implies that changes and extensions to the model will be required from time to time. Therefore, it is essential to have a model code that can be easily maintained and modified. LISFLOOD has been specifically developed to satisfy these requirements. The model is designed to be applied across a wide range of spatial and temporal scales. LISFLOOD is grid-based, and applications so far have employed grid cells of as little as 100 metres for medium-sized catchments, to 5000 metres for modelling the whole of Europe and up to 0.1° (around 10 km) for modelling globally. Long-term water balance can be simulated (using a daily time step), as well as individual flood events (using hourly time intervals, or even smaller). The output of a “water balance run” can be used to provide the initial conditions of a “flood run”. Although the model’s primary output product is channel discharge, all internal rate and state variables (soil moisture, for example) can be written as output as well. In addition, all output can be written as grids, or time series at user-defined points or areas. The user has complete control over how output is written, thus minimising any waste of disk space or CPU time.
About LISFLOOD
The LISFLOOD model is implemented in the PCRaster Environmental Modelling language Version 3.0.0 (Wesseling et al., 1996), wrapped in a Python based interface. PCRaster is a raster GIS environment that has its own high-level computer language, which allows the construction of iterative spatio-temporal environmental models. The Python wrapper of LISFLOOD enables the user to control the model inputs and outputs and the selection of the model modules. This approach combines the power, relative simplicity and maintainability of code written in the the PCRaster Environmental Modelling language and the flexibility of Python. LISFLOOD runs on any operating for which Python and PCRaster are available. Currently these include 32-bits Windows (e.g. Windows XP, Vista, 7) and a number of Linux distributions.

About this User Manual
This revised User Manual documents LISFLOOD version September 2013, and replaces all previous documentation of the model (e.g. van der Knijff & de Roo, 2008; de Roo et. al., 2003). The scope of this document is to give model users all the information that is needed for successfully using LISFLOOD.

Chapter 2 explains the theory behind the model, including all model equations and the changes to the previous version. The remaining chapters cover all practical aspects of working with LISFLOOD. Chapter 3 to 8 explains how to setup LISFLOOD, how to modify the settings and the outputs.

A series of Annexes at the end of this document describe some optional features that can be activated when running the model. Most model users will not need these features (which are disabled by default), and for the sake of clarity we therefore decided to keep their description out of the main text. The current document does not cover the calculation of the potential evapo(transpiration) rates that are needed as input to the model. A separate pre-processor (LISVAP) exists that calculates these variables from standard (gridded) meteorological observations. LISVAP is documented in a separate volume (van der Knijff, 2006).
2. Process descriptions

Overview
Figure 2.1 gives an overview of the structure of the LISFLOOD model. Basically, the model is made up of the following components:

- a 2-layer soil water balance sub-model
- sub-models for the simulation of groundwater and subsurface flow (using 2 parallel interconnected linear reservoirs)
- a sub-model for the routing of surface runoff to the nearest river channel
- a sub-model for the routing of channel flow (not shown in the Figure)

The processes that are simulated by the model include snow melt (not shown in the Figure), infiltration, interception of rainfall, leaf drainage, evaporation and water uptake by vegetation, surface runoff, preferential flow (bypass of soil layer), exchange of soil moisture between the two soil layers and drainage to the groundwater, sub-surface and groundwater flow, and flow through river channels. Each of these processes is described in more detail in the following.
Figure 2.1 Overview of the LISFLOOD model. P = precipitation; Int = interception; EW$_{int}$ = evaporation of intercepted water; D$_{int}$ = leaf drainage; ES$_a$ = evaporation from soil surface; T$_a$ = transpiration (water uptake by plant roots); INF$_{act}$ = infiltration; Rs = surface runoff; D$_{1,2}$ = drainage from top- to subsoil; D$_{2,gw}$ = drainage from subsoil to upper groundwater zone; D$_{pref,gw}$ = preferential flow to upper groundwater zone; D$_{uz,lz}$ = drainage from upper- to lower groundwater zone; Q$_{uz}$ = outflow from upper groundwater zone; Q$_l$ = outflow from lower groundwater zone; D$_{loss}$ = loss from lower groundwater zone. Note that snowmelt is not included in the Figure (even though it is simulated by the model).
Treatment of meteorological input variables

The meteorological conditions provide the driving forces behind the water balance. LISFLOOD uses the following meteorological input variables:

\[
\begin{align*}
P & : \text{Precipitation} & \text{[mm day}^{-1}] \\
ET0 & : \text{Potential (reference) evapotranspiration rate} & \text{[mm day}^{-1}] \\
EW0 & : \text{Potential evaporation rate from open water surface} & \text{[mm day}^{-1}] \\
ES0 & : \text{Potential evaporation rate from bare soil surface} & \text{[mm day}^{-1}] \\
T_{\text{avg}} & : \text{Average daily temperature}^1 & \text{[}°\text{C}]
\end{align*}
\]

Both precipitation and evaporation are internally converted from \textit{intensities} [mm day\(^{-1}\)] to \textit{quantities per time step} [mm] by multiplying them with the time step, \(\Delta t\) (in days). For the sake of consistency, all in- and outgoing fluxes will also be described as \textit{quantities per time step} [mm] in the following, unless stated otherwise. \(ET0, EW0\) and \(ES0\) can be calculated using standard meteorological observations. To this end a dedicated pre-processing application has been developed (LISVAP), which is documented in a separate volume (van der Knijff, 2006).

Rain and snow

If the average temperature is below 1\(^°\)C, all precipitation is assumed to be snow. A snow correction factor is used to correct for undercatch of snow precipitation. Unlike rain, snow accumulates on the soil surface until it melts. The rate of snowmelt is estimated using a simple degree-day factor method. Degree-day factor type snow melt models usually take the following form (e.g. see WMO, 1986):

\[ M = C_m(T_{\text{avg}} - T_m) \tag{2-1} \]

where \(M\) is the rate of snowmelt, \(T_{\text{avg}}\) is the average daily temperature, \(T_m\) is some critical temperature and \(C_m\) is a degree-day factor [mm \(°\text{C}^{-1}\) day\(^{-1}\)]. Speers \textit{et al.} (1979) developed an extension of this equation which accounts for accelerated snowmelt that takes place when it is raining (cited in Young, 1985). The equation is supposed to apply when rainfall is greater than 30 mm in 24 hours. Moreover, although the equation is reported to work sufficiently well in forested areas, it is not valid in areas that are above the tree line, where radiation is the main energy source for snowmelt. LISFLOOD uses a variation on the equation of Speers \textit{et al.} The modified equation simply assumes that for each mm of rainfall, the rate of snowmelt increases with 1\% (compared to a ‘dry’ situation). This yields the following equation:

\[^1\text{Note that the model needs } \text{daily}\text{ average temperature values, even if the model is run on a smaller time interval (e.g. hourly). This is because the routines for snowmelt and soil freezing are use empirical relations which are based on daily temperature data. Just as an example, feeding hourly temperature data into the snowmelt routine can result in a gross overestimation of snowmelt. This is because even on a day on which the average temperature is below } T_m \text{ (no snowmelt), the instantaneous (or hourly) temperature may be higher for a part of the day, leading to unrealistically high simulated snowmelt rates.}\]
\[ M = C_m \cdot C_{\text{Seasonal}}(1 + 0.01 \cdot R \Delta t)(T_{\text{avg}} - T_m) \cdot \Delta t \]  

where \( M \) is the snowmelt per time step [mm], \( R \) is rainfall (not snow!) intensity [mm day\(^{-1}\)], and \( \Delta t \) is the time interval [days]. \( T_m \) has a value of 0 °C, and \( C_m \) is a degree-day factor [mm °C\(^{-1}\) day\(^{-1}\)]. However, it should be stressed that the value of \( C_m \) can actually vary greatly both in space and time (e.g. see Martinec et al., 1998).

Therefore, in practice this parameter is often treated as a calibration constant. A low value of \( C_m \) indicates slow snow melt. \( C_{\text{Seasonal}} \) is a seasonal variable melt factor which is also used in several other models (e.g. Anderson 2006, Viviroli et al., 2009). There are mainly two reasons to use a seasonally variable melt factor:

- The solar radiation has an effect on the energy balance and varies with the time of the year.
- The albedo of the snow has a seasonal variation, because fresh snow is more common in the mid winter and aged snow in the late winter/spring. This produce an even greater seasonal variation in the amount of net solar radiation.

Figure 2.2 shows an example where a mean value of: 3.0 mm °C\(^{-1}\) d\(^{-1}\) is used. The value of \( C_m \) is reduced by 0.5 at 21\(^{st}\) December and a 0.5 is added on the 21\(^{st}\) June. In between a sinus function is applied.

**Figure 2.2 Sinus shaped snow melt coefficient \((C_m)\) as a function of days of year**

At high altitudes, where the temperature never exceeds 1°C, the model accumulates snow without any reduction because of melting loss. In these altitudes runoff from glacier melt is an important part. The snow will accumulate and converted into firn. Then firn is converted to ice and transported to the lower regions. This can take decades or even hundred years. In the ablation area the ice is melted. In LISFLOOD this process is emulated by melting the snow in higher altitudes on an annual basis over summer. A sinus function is used to start ice melting in summer, starting on the 15 June and ending on the 15 September (see fig 2.3) and using the temperature of zone B (see fig 2.3.)
Figure 2.3  *Sinus shaped ice melt coefficient as a function of days of year*

The amount of snowmelt and icemelt together can never exceed the actual snow cover that is present on the surface.

For large pixel sizes, there may be considerable sub-pixel heterogeneity in snow accumulation and melt, which is a particular problem if there are large elevation differences within a pixel. Because of this, snow melt and accumulation are modelled separately for 3 separate elevation zones, which are defined at the sub-pixel level. This is shown in Figure 2.4.

The division in elevation zones was changed from a uniform distribution in the previous LISFLOOD version to a normal distribution, which fits better to the real distribution of e.g. 100m SRTM DEM pixels in a 5x5km grid cell. 3 elevation zones A, B, and C are defined with each zone occupying one third of the pixel surface. Assuming further that $T_{avg}$ is valid for the average pixel elevation, average temperature is extrapolated to the centroids of the lower (A) and upper (C) elevation zones, using a fixed temperature lapse rate, $L$, of 0.0065 °C per meter elevation difference. Snow, snowmelt and snow accumulation are subsequently modelled separately for each elevation zone, assuming that temperature can be approximated by the temperature at the centroid of each respective zone.
**Figure 2.4** Definition of sub-pixel elevation zones for snow accumulation and melt modelling. Snowmelt and accumulation calculations in each zone are based on elevation (and derived temperature) in centroid of each zone.

- **StD**: Standard Deviation of the DEM
- **quant**: 0.9674 Quantile of the normal distribution: $u_{0.833}=0.9674$
- **L**: temperature lapse rate.

---

**Frost index soil**

When the soil surface is frozen, this affects the hydrological processes occurring near the soil surface. To estimate whether the soil surface is frozen or not, a frost index $F$ is calculated. The equation is based on Molnau & Bissell (1983, cited in Maidment 1993), and adjusted for variable time steps. The rate at which the frost index changes is given by:

$$\frac{dF}{dt} = -(1 - A_f)F - T_{av} \cdot e^{-0.04Kd_s/we_s}$$  \hspace{1cm} (2.4)$$

$dF/dt$ is expressed in [$°C$ day$^{-1}$ day$^{-1}$]. $A_f$ is a decay coefficient [day$^{-1}$], $K$ is a a snow depth reduction coefficient [cm$^{-1}$], $d_s$ is the (pixel-average) depth of the snow cover (expressed as mm equivalent water depth), and $we_s$ is a parameter called snow water equivalent, which is the equivalent water depth water of a snow cover (Maidment, 1993). In LISFLOOD, $A_f$ and $K$ are set to 0.97 and 0.57 cm$^{-1}$ respectively, and $we_s$ is taken as 0.1, assuming an average snow density of 100 kg/m$^3$ (Maidment, 1993). The soil is considered frozen when the frost index
rises above a critical threshold of 56. For each time step the value of \( F [^\circ \text{C day}^{-1}] \) is updated as:

\[
F(t) = F(t-1) + \frac{dF}{dt} \Delta t
\]  

(2-5)

\( F \) is not allowed to become less than 0.

When the frost index rises above a threshold of 56, every soil process is frozen and transpiration, evaporation, infiltration and the outflow to the second soil layer and to upper groundwater layer is set to zero. Any rainfall is bypassing the soil and transformed into surface runoff till the frost index is equal or less than 56.

**Adressing sub-grid variability in land cover**

In the previous versions of LISFLOOD a number of parameters are linked directly to land cover classes by using lookup tables. The spatially dominant value has been used to assign the corresponding grid parameter values. This implies that some of the sub-grid variability in land use, and consequently in the parameter of interest, is lost (figure 2.5).

**Figure 2.5** Land cover aggregation approach in previous versions of LISFLOOD

In order account properly for land use dynamics, some conceptual changes have been made to render LISFLOOD more land-use sensitive. To account for the sub-grid variability in land use, we model the within-grid variability. In the modified version of the hydrological model, the spatial distribution and frequency of each class is defined as a percentage of the whole represented area of the new pixel. Combining land cover classes and modeling aggregated classes, is known as the concept of hydrological response units (HRU). The logic behind this approach is that the non-linear nature of the rainfall runoff processes on different land cover surfaces observed in reality will be better captured. This concept is also used in models such as SWAT (Arnold and Fohrer, 2005) and PREVAH (Viviroli et al., 2009). LISFLOOD has been transferred a HRU approach on sub-grid level, as shown in figure 2.6.
Figure 2.6 LISFLOOD land cover aggregation by modelling aggregated land use classes separately: Percentages of forest (dark green); water (blue), impervious surface (red), other classes (light green)

Soil model

If a part of a pixel is made up of built-up areas this will influence that pixel's water-balance. LISFLOOD's 'direct runoff fraction' parameter ($f_{dr}$) defines the fraction of a pixel that is impervious. For impervious areas, LISFLOOD assumes that:

1. A depression storage is filled by precipitation and snowmelt and emptied by evaporation
2. Any water that is not filling the depression storage, reaches the surface is added directly to surface runoff
3. The storage capacity of the soil is zero (i.e. no soil moisture storage in the direct runoff fraction)
4. There is no groundwater storage

For open water (e.g. lakes, rivers) the water fraction parameter ($f_{water}$) defines the fraction that is covered with water (large lakes that are in direct connection with major river channels can be modelled using LISFLOOD's lake option, which is described in Annex 5 of this manual). For water covered areas, LISFLOOD assumes that:

1. The loss of actual evaporation is equal to the potential evaporation on open water
2. Any water that is not evaporated, reaches the surface is added directly to surface runoff
3. The storage capacity of the soil is zero (i.e. no soil moisture storage in the water fraction)
4. There is no groundwater storage
For the part of a pixel that is forest \((f_{\text{forest}})\) or other land cover \((f_{\text{other}}=1-f_{\text{forest}}-f_{\text{dr}}-f_{\text{water}})\) the description of all soil- and groundwater-related processes below (evaporation, transpiration, infiltration, preferential flow, soil moisture redistribution and groundwater flow) are valid. While the modelling structure for forest and other classes is the same, the difference is the use of different map sets for leaf area index, soil and soil hydraulic properties. Because of the nonlinear nature of the rainfall runoff processes this should yield better results than running the model with average parameter values. Table 2 summarises the profiles of the four individually modelled categories of land cover classes.

### Table 2.1 Summary of hydrological properties of the four categories modelled individually in the modified version of LISFLOOD.

If you activate any of LISFLOOD’s options for writing internal model fluxes to time series or maps (described in Chapter 8), the model will report the real fluxes, which are the fluxes multiplied by the corresponding fraction. Figure 2.7 illustrates this for evapotranspiration (evaporation and transpiration) which calculated differently for each of this four aggregated classes. The total sum of evapotranspiration for a pixel is calculated by adding up the fluxes for each class multiplied by the fraction of each class.
Figure 2.7 Simulation of aggregated land cover classes in LISFLOOD. In this example, evapotranspiration (ET) is simulated for each aggregated class separately (ET$_{forest}$, ET$_{dr}$, ET$_{water}$, ET$_{other}$).

As result of the soil model you get four different surface fluxes weighted by the corresponding fraction ($f_{dr}$, $f_{water}$, $f_{forest}$, $f_{other}$), respectively two fluxes for the upper and lower groundwater zone and for groundwater loss also weighted by the corresponding fraction ($f_{forest}$, $f_{other}$). However a lot of the internal flux or states (e.g. preferential flow for forested areas) can be written to disk as map or timeseries by activate LISFLOOD’s options (described in Chapter 8).

**Interception**

Interception is estimated using the following storage-based equation (Aston, 1978, Merriam, 1960):

\[
Int = S_{max} \cdot [1 - \exp(-k \cdot R \Delta t / S_{max})]
\]

where $Int$ [mm] is the interception per time step, $S_{max}$ [mm] is the maximum interception, $R$ is the rainfall intensity [mm day$^{-1}$] and the factor $k$ accounts for the density of the vegetation. $S_{max}$ is calculated using an empirical equation (Von Hoyningen-Huene, 1981):

\[
S_{max} = \begin{cases} 
0.935 + 0.498 \cdot LAI - 0.00575 \cdot LAI^2 & \text{[LAI > 0.1]} \\
0 & \text{[LAI \leq 0.1]}
\end{cases}
\]

(2-7)

where $LAI$ is the average Leaf Area Index [m$^2$ m$^{-2}$] of each model element (pixel).

$k$ is estimated as:

\[
k = 0.046 \cdot LAI
\]

(2-8)
The value of \( Int \) can never exceed the interception storage capacity, which is defined as the difference between \( S_{\text{max}} \) and the accumulated amount of water that is stored as interception, \( Int_{\text{cum}} \).

**Evaporation of intercepted water**

Evaporation of intercepted water, \( EW_{\text{int}} \), occurs at the potential evaporation rate from an open water surface, \( EW0 \). The *maximum* evaporation per time step is proportional to the fraction of vegetated area in each pixel (Supit *et al.*, 1994):

\[
EW_{\text{max}} = EW0 \cdot [1 - \exp(-\kappa_{gb} \cdot LAI)] \Delta t
\]

(2-9)

where \( EW0 \) is the potential evaporation rate from an open water surface [mm day\(^{-1}\)], and \( EW_{\text{max}} \) is in [mm] per time step. Constant \( \kappa_{gb} \) is the extinction coefficient for global solar radiation [-]. Since evaporation is limited by the amount of water stored on the leaves, the actual amount of evaporation from the interception store equals:

\[
EW_{\text{int}} = \min(EW_{\text{max}} \cdot \Delta t, Int_{\text{cum}})
\]

(2-10)

where \( EW_{\text{int}} \) is the actual evaporation from the interception store [mm] per time step, and \( EW0 \) is the potential evaporation rate from an open water surface [mm day\(^{-1}\)].

It is assumed that on average all water in the interception store (\( Int_{\text{cum}} \)) will have evaporated or fallen to the soil surface as leaf drainage within one day. Leaf drainage is therefore modelled as a linear reservoir with a time constant (or residence time) of one day, i.e:

\[
D_{\text{int}} = \frac{1}{T_{\text{int}}} \cdot Int_{\text{cum}} \Delta t
\]

(2-11)

where \( D_{\text{int}} \) is the amount of leaf drainage per time step [mm] and \( T_{\text{int}} \) is a time constant for the interception store [days], which is set to 1 day.
**Water available for infiltration and direct runoff**

In the permeable fraction of each pixel \((1 \cdot f_{dr})\), the amount of water that is available for infiltration, \(W_{av}[\text{mm}]\) equals (Supit et al., 1994):

\[
W_{av} = R \Delta t + M + D_{int} - Int
\]  

(2-12)

where:

- \(R\) : Rainfall \([\text{mm} \text{ day}^{-1}]\)
- \(M\) : Snow melt \([\text{mm}]\)
- \(D_{int}\) : Leaf drainage \([\text{mm}]\)
- \(Int\) : Interception \([\text{mm}]\)
- \(\Delta t\) : time step \([\text{days}]\)

Since no infiltration can take place in each pixel’s ‘direct runoff fraction’, direct runoff is calculated as:

\[
R_d = f_{dr} \cdot W_{av}
\]  

(2-13)

where \(R_d\) is in \([\text{mm}]\) per time step. Note here that \(W_{av}\) is valid for the permeable fraction only, whereas \(R_d\) is valid for the direct runoff fraction.

**Water uptake by plant roots and transpiration**

Water uptake and transpiration by vegetation and direct evaporation from the soil surface are modelled as two separate processes. The approach used here is largely based on Supit et al. (1994) and Supit & Van Der Goot (2000). The maximum transpiration per time step \([\text{mm}]\) is given by:

\[
T_{\text{max}} = k_{\text{crop}} \cdot ET0 \cdot [1 - \exp(-k_{gb} \cdot LAI)] \Delta t - EW_{int}
\]  

(2-14)

Where \(ET0\) is the potential (reference) evapotranspiration rate \([\text{mm} \text{ day}^{-1}]\), \(k_{gb}\) is the extinction coefficient for global solar radiation \([-\] \] and \(k_{\text{crop}}\) is a crop coefficient, a ration between the potential (reference) evapotranspiration rate and the potential evaporation rate of a specific crop. \(k_{\text{crop}}\) is 1 for most vegetation types, except for some excessively transpiring crops like sugarcane or rice.

Note that the energy that has been ‘consumed’ already for the evaporation of intercepted water is simply subtracted here in order to respect the overall energy balance. The actual transpiration rate is reduced when the amount of moisture in the soil is small. In the model, a reduction factor is applied to simulate this effect:

\[
r_{W3} = \frac{(w_1 - w_{upl})}{(w_{crit} - w_{upl})}
\]  

(2-15)
where $w_1$ is the amount of moisture in the upper soil layer [mm], $w_{wp1}$ [mm] is the amount of soil moisture at wilting point (soil moisture potential pF 4.2) and $w_{crit1}$ [mm] is the amount of moisture below which water uptake is reduced and plants start closing their stomata. The critical amount of soil moisture is calculated as:

$$w_{crit1} = (1 - p) \cdot (w_{fcl1} - w_{wp1}) + w_{wp1} \quad (2-16)$$

where $w_{fcl1}$ [mm] is the amount of soil moisture at field capacity and $p$ is the soil water depletion fraction. $R_{WS}$ varies between 0 and 1: negative values and values greater than 1 are truncated to 0 and 1, respectively. $p$ represents the fraction of soil moisture between $w_{fcl1}$ and $w_{wp1}$ that can be extracted from the soil without reducing the transpiration rate. Its value is a function of both vegetation type and the potential evapotranspiration rate. The procedure to estimate $p$ is described in detail in Supit & Van Der Goot (2003). Figure 2.8 further illustrates the relation between $R_{WS}$, $w$, $w_{crit}$, $w_{fcl}$, $w_{wp}$.

**Figure 2.8** Reduction of transpiration in case of water stress. $R_{ws}$ decreases linearly to zero between $w_{crit}$ and $w_{wp}$.

</table>
The actual transpiration $T_a$ is now calculated as:

$$T_a = r_{WS} \cdot T_{\text{max}} \quad (2-17)$$

with $T_a$ and $T_{\text{max}}$ in [mm].

Transpiration is set to zero when the soil is frozen (i.e. when frost index $F$ exceeds its critical threshold). The amount of moisture in the upper soil layer is updated after the transpiration calculations:

$$w_i = w_i - T_a \quad (2-18)$$

**Direct evaporation from the soil surface**

The maximum amount of evaporation from the soil surface equals the maximum evaporation from a shaded soil surface, $ES_{\text{max}}$ [mm], which is computed as:

$$ES_{\text{max}} = ES_0 \cdot \exp(-\kappa_{eb} \cdot LAI) \Delta t \quad (2-19)$$

where $ES_0$ is the potential evaporation rate from bare soil surface [mm day$^{-1}$]. The actual evaporation from the soil mainly depends on the amount of soil moisture near the soil surface: evaporation decreases as the topsoil is drying. In the model this is simulated using a reduction factor which is a function of the number of days since the last rain storm (Stroosnijder, 1987, 1982):

$$ES_a = ES_{\text{max}} \cdot (\sqrt{D_{slr}} - \sqrt{D_{slr} - 1}) \quad (2-20)$$

The variable $D_{slr}$ represents the number of days since the last rain event. Its value accumulates over time: if the amount of water that is available for infiltration ($W_{av}$) remains below a critical threshold it increases by an amount of $\Delta t$ [days] for each time step. It is reset to 1 only if the critical amount of water is exceeded$^2$. The actual soil evaporation is always the smallest value out of the result of the equation above and the available amount of moisture in the soil, i.e.:

$$ES_a = \min(ES_a, w_i - w_{\text{rest}}) \quad (2-21)$$

where $w_i$ [mm] is the amount of moisture in the upper soil layer and $w_{\text{rest}}$ [mm] is the residual amount of soil moisture. Like transpiration, direct evaporation from the soil is set to zero if the soil is frozen. The amount of moisture in the upper soil layer is updated after the evaporation calculations:

$$w_i = w_i - ES_a \quad (2-22)$$

$^2$ In the LISFLOOD settings file this critical amount is currently expressed as an intensity [mm day$^{-1}$]. This is because the equation was originally designed for a daily time step only. Because the current implementation will likely lead to $D_{slr}$ being reset too frequently, the exact formulation may change in future versions (e.g. by keeping track of the accumulated available water of the last 24 hours).
**Infiltration capacity**

The infiltration capacity of the soil is estimated using the widely-used Xinanjiang (also known as VIC/ARNO) model (e.g. Zhao & Lui, 1995; Todini, 1996). This approach assumes that the fraction of a grid cell that is contributing to surface runoff (read: saturated) is related to the total amount of soil moisture, and that this relationship can be described through a non-linear distribution function. For any grid cell, if \( w_1 \) is the total moisture storage in the upper soil layer and \( w_s \) is the maximum storage, the corresponding saturated fraction \( A_s \) is approximated by the following distribution function:

\[
A_s = 1 - \left(1 - \frac{w_1}{w_s}\right)^b
\]  

(2-23)

where \( w_s \) and \( w_1 \) are the maximum and actual amounts of moisture in the upper soil layer, respectively [mm], and \( b \) is an empirical shape parameter. In the LISFLOOD implementation of the Xinanjiang model, \( A_s \) is defined as a fraction of the permeable fraction of each pixel (i.e. as a fraction of \((1-d_{rf})\)). The infiltration capacity \( INF_{pot} \) [mm] is a function of \( w_s \) and \( A_s \):

\[
INF_{pot} = \frac{w_s}{b+1} - \frac{w_1}{b+1} \left[1 - \left(1 - A_s\right)^b\right]
\]  

(2-24)

Note that the shape parameter \( b \) is related to the heterogeneity within each grid cell. For a totally homogeneous grid cell \( b \) approaches zero, which reduces the above equations to a simple ‘overflowing bucket’ model. Before any water is draining from the soil to the groundwater zone the soil has to be completely filled up. See also red line in figure 2.9: e.g. a soil of 60% soil moisture has 40% potential infiltration capacity. A \( b \) value of 1.0 is comparable to a leaking bucket. See black line in figure 2.9: e.g. a soil of 60% soil moisture has only 10% potential infiltration capacity while 30% is draining directly to groundwater. Increasing \( b \) even further than 1 is comparable to a sieve (see figure 2.10). Most of the water is going directly to groundwater and the potential infiltration capacity is going toward 0.
Soil moisture and potential infiltration capacity relation

**Figure 2.9** Soil moisture and potential infiltration capacity relation

Preferential bypass flow

For the simulation of preferential bypass flow –i.e. flow that bypasses the soil matrix and drains directly to the groundwater- no generally accepted equations exist. Because ignoring preferential flow completely will lead to unrealistic model behaviour during extreme rainfall conditions, a very simple approach is used in LISFLOOD. During each time step, a fraction of the water that is available for infiltration is added to the groundwater directly (i.e. without first entering the soil matrix). It is assumed that this fraction is a power function of the relative saturation of the topsoil, which results in an equation that is somewhat similar to the excess soil water equation used in the HBV model (e.g. Lindström et al., 1997):
\[ D_{\text{pref, gw}} = W_{\text{av}} \left( \frac{W_1}{W_2} \right)^{c_{\text{pref}}} \]  

(2-25)

where \( D_{\text{pref, gw}} \) is the amount of preferential flow per time step [mm], \( W_{\text{av}} \) is the amount of water that is available for infiltration, and \( c_{\text{pref}} \) is an empirical shape parameter. \( f_{\text{dr}} \) is the ‘direct runoff fraction’ [-], which is the fraction of each pixel that is made up by urban area and open water bodies (i.e. preferential flow is only simulated in the permeable fraction of each pixel). The equation results in a preferential flow component that becomes increasingly important as the soil gets wetter.

Figure 2.11 shows with \( c_{\text{pref}} = 0 \) (red line) every available water for infiltration is converted into preferential flow and bypassing the soil. \( c_{\text{pref}} = 1 \) (black line) gives a linear relation e.g. at 60% soil saturation 60% of the available water is bypassing the soil matrix. With increasing \( c_{\text{pref}} \) the percentage of preferential flow is decreasing.

![Figure 2.11 Soil moisture and preferential flow relation](image)

**Actual infiltration and surface runoff**

The actual infiltration \( \text{INF}_{\text{act}} \) [mm] is now calculated as:

\[ \text{INF}_{\text{act}} = \min( \text{INF}_{\text{pot}}, W_{\text{av}} - D_{\text{pref, gw}} ) \]  

(2-26)

Finally, the surface runoff \( R_s \) [mm] is calculated as:

\[ R_s = R_d + (1 - f_{\text{dr}}) \cdot (W_{\text{av}} - D_{\text{pref, gw}} - \text{INF}_{\text{act}}) \]  

(2-27)
where $R_d$ is the direct runoff (generated in the pixel’s ‘direct runoff fraction’). If the soil is frozen ($F >$ critical threshold) no infiltration takes place. The amount of moisture in the upper soil layer is updated after the infiltration calculations:

$$w_i = w_i + INF_{act} \quad (2-28)$$

**Soil moisture redistribution**

The description of the moisture fluxes out of the subsoil (and also between the upper- and lower soil layer) is based on the simplifying assumption that the flow of soil moisture is entirely gravity-driven. Starting from Darcy’s law for 1-D vertical flow:

$$q = -K(\theta)\left[\frac{\partial h(\theta)}{\partial z} - 1\right] \quad (2-29)$$

where $q$ [mm day$^{-1}$] is the flow rate out of the soil (e.g. upper soil layer, lower soil layer); $K(\theta)$ [mm day$^{-1}$] is the hydraulic conductivity (as a function of the volumetric moisture content of the soil, $\theta$ [mm$^3$ mm$^{-3}$]) and $\partial h(\theta)/\partial z$ is the matric potential gradient. If we assume a matric potential gradient of zero, the equation reduces to:

$$q = K(\theta) \quad (2-30)$$

This implies a flow that is always in downward direction, at a rate that equals the conductivity of the soil. The relationship between hydraulic conductivity and soil moisture status is described by the Van Genuchten equation (van Genuchten, 1980), here re-written in terms of mm water slice, instead of volume fractions:

$$K(w) = K_s \left( \frac{w - w_r}{w_s - w_r} \right)^{1/2} \left[1 - \left(\frac{w - w_r}{w_s - w_r}\right)^{1/m}\right]^{-2} \quad (2-31)$$

where $K_s$ is the saturated conductivity of the soil [mm day$^{-1}$], and $w$, $w_r$ and $w_s$ are the actual, residual and maximum amounts of moisture in the soil respectively (all in [mm]). Parameter $m$ is calculated from the pore-size index, $\lambda$ (which is related to soil texture):

$$m = \frac{\lambda}{\lambda + 1} \quad (2-32)$$

For large values of $\Delta t$ (e.g. 1 day) the above equation often results in amounts of outflow that exceed the available soil moisture storage, i.e:

$$K(w)\Delta t > w - w_r \quad (2-33)$$

In order to solve the soil moisture equations correctly an iterative procedure is used. At the beginning of each time step, the conductivities for both soil layers [$K_1(w_1), K_2(w_2)$] are calculated using the Van Genuchten equation. Multiplying
these values with the time step and dividing by the available moisture gives a Courant-type numerical stability indicator for each respective layer:

\[
C_1 = \frac{K_1(w_1) \cdot \Delta t}{w'_1 - w_{r1}} \tag{2-34a}
\]

\[
C_2 = \frac{K_2(w_2) \cdot \Delta t}{w'_2 - w_{r2}} \tag{2-34b}
\]

A Courant number that is greater than 1 implies that the calculated outflow exceeds the available soil moisture, resulting in loss of mass balance. Since we need a stable solution for both soil layers, the ‘overall’ Courant number for the soil moisture routine is the largest value of \( C_1 \) and \( C_2 \):

\[
C_{\text{soil}} = \max(C_1, C_2) \tag{2-35}
\]

In principle, rounding \( C_{\text{soil}} \) up to the nearest integer gives the number sub-steps needed for a stable solution. In practice, it is often preferable to use a critical Courant number that is lower than 1, because high values can result in unrealistic ‘jumps’ in the simulated soil moisture pattern when the soil is near saturation (even though mass balance is preserved). Hence, making the critical Courant number a user-defined value \( C_{\text{crit}} \), the number of sub-steps becomes:

\[
\text{SubSteps} = \text{roundup}\left(\frac{C_{\text{soil}}}{C_{\text{crit}}}\right) \tag{2-36}
\]

and the corresponding sub-time-step, \( \Delta' t \):

\[
\Delta' t = \frac{\Delta t}{\text{SubSteps}} \tag{2-37}
\]

In brief, the iterative procedure now involves the following steps. First, the number of sub-steps and the corresponding sub-time-step are computed as explained above. The amounts of soil moisture in the upper and lower layer are copied to temporary variables \( w'_1 \) and \( w'_2 \). Two variables, \( D_{1,2} \) (flow from upper to lower soil layer) and \( D_{2,\text{gw}} \) (flow from lower soil layer to groundwater) are initialized (set to zero). Then, for each sub-step, the following sequence of calculations is performed:

1. compute hydraulic conductivity for both layers
2. compute flux from upper to lower soil layer for this sub-step (\( D'_{1,2} \), can never exceed storage capacity in lower layer):

\[
D'_{1,2} = \min[K_1(w'_1) \Delta t, w'_{x2} - w'_2] \tag{2-38}
\]
3. compute flux from lower soil layer to groundwater for this sub-step \((D'_{2,\text{gw}}, \text{can never exceed available water in lower layer}):\)

\[
D'_{2,\text{gw}} = \min[K_z (w'_z - w'_{r_2}), \Delta t, w'_{r_2} - w'_z]
\]

(2-39)

4. update \(w'_1\) and \(w'_2\)

5. add \(D'_{1,2}\) to \(D_{1,2}\); add \(D'_{2,\text{gw}}\) to \(D_{2,\text{gw}}\)

If the soil is frozen \((F > \text{critical threshold})\), both \(D_{1,2}\) and \(D_{2,\text{gw}}\) are set to zero. After the iteration loop, the amounts of soil moisture in both layers are updated as follows:

\[
w_1 = w_1 - D_{1,2}
\]

(2-40)

\[
w_2 = w_2 + D_{1,2} - D_{2,\text{gw}}
\]

(2-41)

**Groundwater**

Groundwater storage and transport are modelled using two parallel linear reservoirs, similar to the approach used in the HBV-96 model (Lindström et al., 1997). The upper zone represents a quick runoff component, which includes fast groundwater and subsurface flow through macro-pores in the soil. The lower zone represents the slow groundwater component that generates the base flow.

The outflow from the upper zone to the channel, \(Q_{uz} [\text{mm}]\) equals:

\[
Q_{uz} = \frac{1}{T_{uz}} \cdot UZ \Delta t
\]

(2-42)

where \(T_{uz}\) is a reservoir constant [days] and \(UZ\) is the amount of water that is stored in the upper zone [mm]. Similarly, the outflow from the lower zone is given by:

\[
Q_{lz} = \frac{1}{T_{lz}} \cdot LZ \Delta t
\]

(2-43)

Here, \(T_{lz}\) is again a reservoir constant [days], and \(LZ\) is the amount of water that is stored in the lower zone [mm]. The values of both \(T_{uz}\) and \(T_{lz}\) are obtained by calibration. The upper zone also provides the inflow into the lower zone. For each time step, a fixed amount of water percolates from the upper to the lower zone:

\[
D_{uz,lz} = \min(GW_{\text{percl}} \cdot \Delta t, UZ)
\]

(2-44)

Here, \(GW_{\text{percl}} [\text{mm day}^{-1}]\) is a user-defined value that can be used as a calibration constant. For many catchments it is quite reasonable to treat the lower groundwater zone as a system with a closed lower boundary (i.e. water is either stored, or added to the channel). However, in some cases the closed boundary
assumption makes it impossible to obtain realistic simulations. Because of this, it is possible to percolate a fixed amount of water out of the lower zone, as a loss $D_{loss}$:

$$D_{loss} = \min(f_{loss} \cdot \Delta t, LZ)$$

(2-45)

In the previous version of LISFLOOD $D_{loss}$ was calculated as a fixed fraction of $Q_{lz}$, but this leads to a high dependency of $D_{loss}$ from $GW_{perc}$ and $LZ$. For example if either $GW_{perc}$ or $LZ$ is quite low the parameter $D_{loss}$ turns out to be meaningless.

The loss fraction, $f_{loss}$ [-], equals 0 for a completely closed lower boundary. If $f_{loss}$ is set to 1, all outflow from the lower zone is treated as a loss. Water that flows out of the lower zone through $D_{loss}$ is quite literally ‘lost’ forever. Physically, the loss term could represent water that is either lost to deep groundwater systems (that do not necessarily follow catchment boundaries), or even groundwater extraction wells. When using the model, it is suggested to use $f_{loss}$ with some care; start with a value of zero, and only use any other value if it is impossible to get satisfactory results by adjusting the other calibration parameters.

At each time step, the amounts of water in the upper and lower zone are updated for the in- and outgoing fluxes, i.e.:

$$UZ_t = UZ_{t-1} + D_{2,gw} - D_{uz,lz} - Q_{uz}$$

(2-46)

$$LZ_t = LZ_{t-1} + D_{uz,lz} - Q_{lz} - D_{loss}$$

(2-47)

Note that these equations are again valid for the permeable fraction of the pixel only: storage in the direct runoff fraction equals 0 for both $UZ$ and $LZ$.

**Routing of surface runoff to channel**

Surface runoff is routed to the nearest downstream channel using a 4-point implicit finite-difference solution of the kinematic wave equations (Chow, 1988). The basic equations used are the equations of continuity and momentum. The continuity equation is:

$$\frac{\partial Q_{sr}}{\partial x} + \frac{\partial A_{sr}}{\partial t} = q_{sr}$$

(2-48)

where $Q_{sr}$ is the surface runoff [m$^3$ s$^{-1}$], $A_{sr}$ is the cross-sectional area of the flow [m$^2$] and $q_{sr}$ is the amount of lateral inflow per unit flow length [m$^2$ s$^{-1}$]. The momentum equation is defined as:

$$\rho g A_{sr} (S_0 - S_f) = 0$$

(2-49)

where $\rho$ is the density of the flow [kg m$^{-3}$], $g$ is the gravity acceleration [m s$^{-2}$], $S_0$ is the topographical gradient and $S_f$ is the friction gradient. From the momentum
equation it follows that $S_0 = S_f$, which means that for the kinematic wave equations it is assumed that the water surface is parallel to the topographical surface. The continuity equation can also be written in the following finite-difference form (please note that for the sake of readability the 'sr' subscripts are omitted here from $Q$, $A$ and $q$):

$$\frac{Q_{i+1}^{j+1} - Q_i^{j+1}}{\Delta x} + \frac{A_{i+1}^{j+1} - A_i^{j+1}}{\Delta t} = \frac{q_{i+1}^{j+1} - q_i^{j+1}}{2}$$  \hspace{1cm} (2-50)

where $j$ is a time index and $i$ a space index (such that $i=1$ for the most upstream cell, $i=2$ for its downstream neighbour, etcetera). The momentum equation can also be expressed as (Chow et al., 1988):

$$A_{sr} = \alpha_{k,sr} Q_{sr}^{\beta_k}$$ \hspace{1cm} (2-51)

Substituting the right-hand side of this expression in the finite-difference form of the continuity equation gives a nonlinear implicit finite-difference solution of the kinematic wave:

$$\frac{\Delta t}{\Delta x} Q_{i+1}^{j+1} + \alpha_k (Q_{i+1}^{j+1})^{\beta_k} = \frac{\Delta t}{\Delta x} Q_i^{j+1} + \alpha_k (Q_i^{j+1})^{\beta_k} + \Delta t \left( \frac{q_{i+1}^{j+1} + q_i^{j+1}}{2} \right)$$ \hspace{1cm} (2-52)

If $\alpha_{k,sr}$ and $\beta_k$ are known, this non-linear equation can be solved for each pixel and during each time step using an iterative procedure. This numerical solution scheme is available as a built-in function in the PCRaster software. The coefficients $\alpha_{k,sr}$ and $\beta_k$ are calculated by substituting Manning’s equation in the right-hand side of Equation 2-51:

$$A_{sr} = \left( \frac{n \cdot P_{sr}^{\gamma}}{S_0^{\gamma/2}} \right)^{\gamma/2} Q_{sr}^{\gamma/2}$$ \hspace{1cm} (2-53)

where $n$ is Manning’s roughness coefficient and $P_{sr}$ is the wetted perimeter of a cross-section of the surface flow. Substituting the right-hand side of this equation for $A_{sr}$ in equation 2-51 gives:

$$\alpha_{k,sr} = \left( \frac{n \cdot P_{sr}^{\gamma/2}}{S_0^{\gamma/2}} \right)^0.6 \hspace{1cm} ; \hspace{1cm} \beta_k = 0.6$$ \hspace{1cm} (2-54)

At present, LISFLOOD uses values for $\alpha_{k,sr}$ which are based on a static (reference) flow depth, and a flow width that equals the pixel size, $\Delta x$. For each time step, all runoff that is generated ($R_s$) is added as side-flow ($q_{sr}$). For each flowpath, the routing stops at the first downstream pixel that is part of the channel network. In other words, the routine only routes the surface runoff to the nearest channel; no runoff through the channel network is simulated at this stage (runoff- and channel routing are completely separated).
**Routing of sub-surface runoff to channel**

All water that flows out of the upper- and lower groundwater zone is routed to the nearest downstream channel pixel within one time step. Recalling once more that the groundwater equations are valid for the pixel’s permeable fraction only, the contribution of each pixel to the nearest channel is made up of \((f_{\text{forest}}+f_{\text{other}})(Q_{uz}+Q_{lz})\). Figure 2.12 illustrates the routing procedure: for each pixel that contains a river channel, its contributing pixels are defined by the drainage network. For every 'river pixel' the groundwater outflow that is generated by its upstream pixels is simply summed. For instance, there are two flow paths that are contributing to the second 'river pixel' from the left in Figure 2.12. Hence, the amount of water that is transported to this pixel equals the sum of the amounts of water produced by these flowpaths, \(q_1 + q_2\). Note that, as with the surface runoff routing, no water is routed *through* the river network at this stage.

![Figure 2.12 Routing of groundwater to channel network. Groundwater flow is routed to the nearest 'channel' pixel.](image)

**Channel routing**

Flow through the channel is simulated using the kinematic wave equations. The basic equations and the numerical solution are identical to those used for the surface runoff routing:

\[
\frac{\partial Q_{ch}}{\partial x} + \frac{\partial A_{ch}}{\partial t} = q_{ch} \tag{2-55}
\]

where \(Q_{ch}\) is the channel discharge [\(m^3 \cdot s^{-1}\)], \(A_{ch}\) is the cross-sectional area of the flow [\(m^2\)] and \(q_{ch}\) is the amount of lateral inflow per unit flow length [\(m^2 \cdot s^{-1}\)]. The momentum equation then becomes:
\[ \rho g A_{ch} (S_0 - S_f) = 0 \]  

where \( S_0 \) now equals the gradient of the channel bed, and \( S_0 = S_f \) as with the surface runoff, values for parameter \( \alpha_{k, ch} \) are estimated using Manning’s equation:

\[ \alpha_{k, ch} = \left( \frac{n \cdot P_{ch}}{S_0} \right)^{2/3} ; \beta_k = 0.6 \]  

At present, LISFLOOD uses values for \( \alpha_{k, ch} \) which are based on a static (reference) channel flow depth (half bankfull) and measured channel dimensions. The term \( q_{ch} \) (sideflow) now represents the runoff that enters the channel per unit channel length:

\[ q_{ch} = \left( \sum Q_{sr} + \sum Q_{uz} + \sum Q_{lz} + Q_{in} + Q_{res} \right) / L_{ch} \]  

Here, \( Q_{sr} \), \( Q_{uz} \) and \( Q_{lz} \) denote the contributions of surface runoff, outflow from the upper zone and outflow from the lower zone, respectively. \( Q_{in} \) is the inflow from an external inflow hydrograph; by default its value is 0, unless the ‘inflow hydrograph’ option is activated (see Annex 2). \( Q_{res} \) is the water that flows out of a reservoir into the channel; by default its value is 0, unless the ‘reservoir’ option is activated (see Annex 1). \( Q_{sr} \), \( Q_{uz} \), \( Q_{lz} \), \( Q_{in} \) and \( Q_{res} \) are all expressed in [\( m^3 \)] per time step. \( L_{ch} \) is the channel length [m], which may exceed the pixel size (\( \Delta x \)) in case of meandering channels. The kinematic wave channel routing can be run using a smaller time-step than the over simulation timestep, \( \Delta t \), if needed.

**Special simulation options**

The above model description covers the processes that are simulated in a ‘standard’ LISFLOOD run. By default, special structures in the river channel e.g. lakes and regulated reservoirs are not taken into account. However, LISFLOOD has some optional features to model these structures. The description of these features can be found in a series of Annexes at the end of this manual.

Features are:
- Including reservoirs, polder, lakes (Annex 1-3)
- Including inflow hydrographs (Annex 4)
- Using a double kinematic wave approach for channel routing (Annex 5)
- Using the diffusion wave approach instead of kinematic wave for channel routing (Annex 6)
- Including transmission loss (Annex 7)
- Using water use maps (Annex 8)
- Simulating water levels (Annex 9)
3. Installation of the LISFLOOD model

System requirements
Currently LISFLOOD is available on both 64-bit Linux and 32-bit Windows systems. Either way, the model requires that a recent version of the PCRaster software is available, or at least PCRaster’s ’pcrcalc’ application and all associated libraries. LISFLOOD require ’pcrcalc’ version November 30, 2009, or more recent. Older ’pcrcalc’ versions will either not work at all, or they might produce erroneous results. Unless you are using a ’sealed’ version of LISFLOOD (i.e. a version in which the source code is made unreadable), you will also need a licensed version of ’pcrcalc’. For details on how to install PCRaster we refer to the PCRaster documentation.

Installation on Windows systems
For Windows users the installation involves two steps:

1. Unzip the contents of ’lisflood_win32.zip’ to an empty folder on your PC (e.g. ’lisflood’)
2. Open the file ’config.xml’ in a text editor. This file contains the full path to all files and applications that are used by LISFLOOD. The items in the file are:
   • Pcrcalc application : this is the name of the pcrcalc application, including the full path
   • LISFLOOD Master Code (optional). This item is usually omitted, and LISFLOOD assumes that the master code is called ’lisflood.xml’, and that it is located in the root of the ’lisflood’ directory (i.e. the directory that contains ’lisflood.exe’ and all libraries). If –for whatever reason- you want to overrule this behaviour, you can add a ’mastercode’ element, e.g:

   <mastercode>d:\Lisflood\mastercode\lisflood.xml</mastercode>

The configuration file should look something like this:

<?xml version="1.0" encoding="ISO-8859-1"?>
<!-- Lisflood configuration file, JvdK, 8 July 2004 -->
<!-- !! This file MUST be in the same directory as lisflood.exe -->
<!-- (or lisflood) !!! -->
<lfconfig>
<!-- location of pcrcalc application -->
<pcrcalcapp>C:\pcraster\apps\pcrcalc.exe</pcrcalcapp>
</lfconfig>

The lisflood executable is a command-line application which can be called from the command prompt (’DOS’ prompt). To make life easier you may include the full path to ’lisflood.exe’ in the ’Path’ environment variable. In Windows XP you can do this by selecting ’settings’ from the ’Start’ menu; then go to ’control panel’/’system’ and go to the ’advanced’ tab. Click on the ‘environment variables’ button. Finally, locate the ’Path’ variable in the ’system variables’ window and click on ’Edit’ (this requires local Administrator privileges).
Installation on Linux systems

Under Linux LISFLOOD requires that the Python interpreter (version 2.5 to 2.7.5) is installed on the system. Most Linux distributions already have Python pre-installed. If needed you can download Python free of any charge from the following location:

http://www.python.org/

The installation process is largely identical to the Windows procedure: unzip the contents of 'lisflood_linux.zip' to an empty directory. Check if the file 'lisflood' is executable. If not, make it executable using:

chmod 755 lisflood

Then update the paths in the configuration file. The configuration file will look something like this:

```xml
<?xml version="1.0" encoding="ISO-8859-1"?>
<!-- Lisflood configuration file, JvdK, 8 July 2004 -->
<!-- !! This file MUST be in the same directory as lisflood.exe -->
<!-- (or lisflood) !!! -->
<lfconfig>
<!-- location of pcrcalc application -->
<!--pcrcalcapp>/software/PCRaster/bin/pcrcalc</pcrcalcapp>
</lfconfig>
```

Running the model

Type 'lisflood' at the command prompt. You should see something like this:

```
LISFLOOD version March 24 2008
Water balance and flood simulation model for large catchments
(C) Institute for Environment and Sustainability
Joint Research Centre of the European Commission
TP261, I-21020 Ispra (Va), Italy

usage (1): lisflood [switches] <InputFile>
usage (2): lisflood --listoptions (show options only)

InputFile : LISFLOOD input file (see documentation for description of format)

switches:
   -s : keep temporary script after simulation
```

You can run LISFLOOD by typing 'lisflood' followed by a specially-formatted settings file. The layout of this file is described in Chapters 4 and 5. Chapter 3 explains all other input files.
4. Model setup: input files

In the current version of LISFLOOD, all model input is provided as either maps (grid files in PCRaster format) or tables. This chapter describes all the data that are required to run the model. Files that are specific to optional LISFLOOD features (e.g. inflow hydrographs, reservoirs) are not listed here; they are described in the documentation for each option.

Input maps

PCRaster requires that all maps must have identical location attributes (number of rows, columns, cellsize, upper x and y coordinate! All input maps roughly fall into any of the following six categories:

- maps related to topography
- maps related to land cover – fraction of land cover
- maps related to land cover and soil
- maps related to soil texture (soil hydraulic properties)
- maps related to channel geometry
- maps related to the meteorological conditions
- maps related to the development of vegetation over time
- maps that define at which locations output is generated as time series

All maps that are needed to run the model are listed in the table\(^3\) of Annex 12.

Role of “mask” and “channels” maps

The mask map (i.e. “area.map”) defines the model domain. In order to avoid unexpected results, it is vital that all maps that are related to topography, land use and soil are defined (i.e. don’t contain a missing value) for each pixel that is “true” (has a Boolean 1 value) on the mask map. The same applies for all meteorological input and the Leaf Area Index maps. Similarly, all pixels that are “true” on the channels map must have some valid (non-missing) value on each of the channel parameter maps. Undefined pixels can lead to unexpected behaviour of the model, output that is full of missing values, loss of mass balance and possibly even model crashes. Some maps need to have values in a defined range e.g. gradient.map has to be greater than 0.

Map location attributes and distance units

LISFLOOD needs to know the size properties of each grid cell (length, area) in order to calculate water volumes from meteorological forcing variables that are all defined as water depths. By default, LISFLOOD obtains this information from the location attributes of the input maps. This will only work if all maps are in an “equal area” (equiareal) projection, and the map co-ordinates (and cell size) are

---

\(^3\) The file names listed in the table are not obligatory. However, it is suggested to stick to the default names suggested in the table. This will make both setting up the model for new catchments as well as upgrading to possible future LISFLOOD versions much easier.
defined in meters. For datasets that use, for example, a latitude-longitude system, neither of these conditions is met. In such cases you can still run LISFLOOD if you provide two additional maps that contain the length and area of each grid cell:

<table>
<thead>
<tr>
<th>Map</th>
<th>Default name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>PixelLengthUser</td>
<td>pixleng.map</td>
<td>Map with pixel length Unit: [m], Range of values: map &gt; 0</td>
</tr>
<tr>
<td>PixelAreaUser</td>
<td>pixarea.map</td>
<td>Map with pixel area Unit: [m²], Range of values: map &gt; 0</td>
</tr>
</tbody>
</table>

Both maps should be stored in the same directory where all other input maps are. The values on both maps may vary in space. A limitation is that a pixel is always represented as a square, so length and width are considered equal (no rectangles). In order to tell LISFLOOD to ignore the default location attributes and use the maps instead, you need to activate the special option “gridSizeUserDefined”, which involves adding the following line to the LISFLOOD settings file:

```
<setoption choice="1" name="gridSizeUserDefined" />
```

LISFLOOD settings files and the use of options are explained in detail in Chapter 5 of this document.

**Naming of meteorological variable maps**

The meteorological forcing variables (and Leaf Area Index) are defined in map stacks. A map stack is simply a series of maps, where each map represents the value of a variable at an individual time step. The name of each map is made up of a total of 11 characters: 8 characters, a dot and a 3-character suffix. Each map name starts with a prefix, and ends with the time step number. All character positions in between are filled with zeros ("0"). Take for example a stack of precipitation maps. Table 4.1 shows that the default prefix for precipitation is "pr", which produces the following file names:

- pr000000.007 : at time step 7
- pr000035.260 : at time step 35260

LISFLOOD can handle two types of stacks. First, there are regular stacks, in which a map is defined for each time step. For instance, the following 10-step stack is a regular stack:
In addition to regular stacks, it is also possible to define *sparse* stacks. A *sparse* stack is a stack in which maps are not defined for all time steps, for instance:

<table>
<thead>
<tr>
<th>t</th>
<th>map name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>pr000000.001</td>
</tr>
<tr>
<td>2</td>
<td>-</td>
</tr>
<tr>
<td>3</td>
<td>-</td>
</tr>
<tr>
<td>4</td>
<td>pr000000.004</td>
</tr>
<tr>
<td>5</td>
<td>-</td>
</tr>
<tr>
<td>6</td>
<td>-</td>
</tr>
<tr>
<td>7</td>
<td>pr000000.007</td>
</tr>
<tr>
<td>8</td>
<td>-</td>
</tr>
<tr>
<td>9</td>
<td>-</td>
</tr>
<tr>
<td>10</td>
<td>-</td>
</tr>
</tbody>
</table>

Here, maps are defined *only* for time steps 1, 4 and 7. In this case, LISFLOOD will use the map values of *pr000000.001* during time steps 1, 2 and 3, those of *pr000000.004* during time steps 4, 5 and 6, and those of *pr000000.007* during time steps 7, 8, 9 and 10. Since both regular and sparse stacks can be combined within one single run, sparse stacks can be very useful to save disk space. For instance, LISFLOOD always needs the *average daily* temperature, even when the model is run on an hourly time step. So, instead of defining 24 identical maps for each hour, you can simply define 1 for the first hour of each day and leave out the rest, for instance:

<table>
<thead>
<tr>
<th>t</th>
<th>map name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>ta000000.001</td>
</tr>
<tr>
<td>2</td>
<td>-</td>
</tr>
<tr>
<td>:</td>
<td>:</td>
</tr>
<tr>
<td>25</td>
<td>ta000000.025</td>
</tr>
<tr>
<td>:</td>
<td>:</td>
</tr>
<tr>
<td>49</td>
<td>ta000000.049</td>
</tr>
<tr>
<td>:</td>
<td>:</td>
</tr>
</tbody>
</table>

Similarly, potential evapo(transpi)ration is usually calculated on a daily basis. So for hourly model runs it is often convenient to define *E0*, *ES0* and *ET0* in sparse stacks as well. Leaf Area Index (*LAI*) is a variable that changes relatively slowly over time, and as a result it is usually advantageous to define *LAI* in a sparse map stack.
**Leaf area index maps**

Because Leaf area index maps follow a yearly circle, only a map stack of one year is necessary which is then used again and again for the following years (this approach can be used for all input maps following a yearly circle e.g. water use). LAI is therefore defined as sparse map stack with a map every 10 days or a month, for example for a monthly changing LAI:

<table>
<thead>
<tr>
<th>t</th>
<th>map name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>lai00000.001</td>
</tr>
<tr>
<td>2</td>
<td>lai00000.032</td>
</tr>
<tr>
<td>3</td>
<td>lai00000.060</td>
</tr>
<tr>
<td>4</td>
<td>lai00000.091</td>
</tr>
<tr>
<td>5</td>
<td>lai00000.121</td>
</tr>
<tr>
<td>6</td>
<td>lai00000.152</td>
</tr>
<tr>
<td>7</td>
<td>lai00000.182</td>
</tr>
<tr>
<td>8</td>
<td>lai00000.213</td>
</tr>
<tr>
<td>9</td>
<td>lai00000.244</td>
</tr>
<tr>
<td>10</td>
<td>lai00000.274</td>
</tr>
<tr>
<td>11</td>
<td>lai00000.305</td>
</tr>
<tr>
<td>12</td>
<td>lai00000.335</td>
</tr>
</tbody>
</table>

After one year the first map is taken again for simulation. For example the simulation started on the 5th March 2010 and the first LAI is lai00000.060. On the 1st March 2011 the map lai00000.060 is taken again as LAI input. To let LISFLOOD know which map has to be used at which day a lookup table (LaiOfDay.txt) is necessary.

**Input tables**

In the previous version of LISFLOOD a number of model parameters are read through tables that are linked to the classes on the land use and soil (texture) maps. Those tables are replaced by maps (e.g. soil hydraulic property maps) in order to include the sub-grid variability of each parameter. Therefore only one table is used in the standard LISFLOOD setting (without lake or reservoir option).

The following table gives an overview:

<table>
<thead>
<tr>
<th>Table</th>
<th>Default name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Day of the year -&gt; LAI</td>
<td>LaiOfDay.txt</td>
<td>Lookup table: Day of the year -&gt; LAI map</td>
</tr>
</tbody>
</table>
**Organisation of input data**

It is up to the user how the input data are organised. However, it is advised to keep the base maps, meteorological maps and tables separated (i.e. store them in separate directories). For practical reasons the following input structure is suggested:

- all base maps are in one directory (e.g. ‘maps’)
  - fraction maps in a subfolder (e.g. ‘fraction’)
  - soil hydraulic properties in a subfolder (e.g. ‘soilhyd’)
  - land cover depending maps in a subfolder (e.g. ‘table2map’)
- all tables are in one directory (e.g. ‘tables’)
- all meteorological input maps are in one directory (e.g. ‘meteo’)
- a folder Leaf Area Index (e.g. ‘lai’)
  - all Leaf Area Index for forest in a subfolder (e.g. ‘forest’)
  - all Leaf Area Index for other in a subfolder (e.g. ‘other’)
- all output goes to one directory (e.g. ‘out’)

The following Figure illustrates this:

*Figure 4.1*  Suggested file structure for LISFLOOD
Generating input base maps
At the time of writing this document, complete sets of LISFLOOD base maps covering the whole of Europe have been compiled at 1- and 5-km pixel resolution. A number of automated procedures have been written that allow you to generate sub-sets of these for pre-defined areas (using either existing mask maps or co-ordinates of catchment outlets).
5. LISFLOOD setup: the settings file

In LISFLOOD, all file and parameter specifications are defined in a settings file. The purpose of the settings file is to link variables and parameters in the model to in- and output files (maps, time series, tables) and numerical values. In addition, the settings file can be used to specify several options. The settings file has a special (XML) structure. In the next sections the general layout of the settings file is explained. Although the file layout is not particularly complex, a basic understanding of the general principles explained here is essential for doing any successful model runs.

The settings file has an XML (‘Extensible Markup Language’) structure. You can edit it using any text editor (e.g. Notepad, Editpad, Emacs, vi). Alternatively, you can also use a dedicated XML editor such as XMLSpy.

**Layout of the settings file**

A LISFLOOD settings file is made up of 4 elements, each of which has a specific function. The general structure of the file is described using XML-tags. XML stands for ‘Extensible Markup Language’, and it is really nothing more than a way to describe data in a file. It works by putting information that goes into a (text) file between tags, and this makes it very easy add structure. For a LISFLOOD settings file, the basic structure looks like this:

```
<lfsettings>
  <lfuser>
  </lfuser>
  <lfoptions>
  </lfoptions>
  <lfbinding>
  </lfbinding>
  <prolog>
  </prolog>
</lfsettings>
```

From this you can see:
The settings file is made up of the elements 'lfuser', 'lfoptions' and 'lfbinding'; in addition, there is a ‘prolog’ element (but this will ultimately disappear in future LISFLOOD versions).

The start of each element is indicated by the element’s name wrapped in square brackets, e.g. `<element>`.

The end of each element is indicated by a forward slash followed by the element’s name, all wrapped in square brackets, e.g. `</element>`.

All elements are part of a ‘root’ element called ‘<lfsettings>’.

In brief, the main function of each element is:

- **lfuser**: definition of paths to all input and output files, and main model parameters (calibration + time-related)
- **lfbinding**: definition of all individual input and output files, and model parameters
- **lfoptions**: switches to turn specific components of the model on or off

The following sections explain the function of each element in more detail. This is mainly to illustrate the main concepts and how it all fits together. A detailed description of all the variables that are relevant for setting up and running LISFLOOD is given in Chapter 6.

**lfuser and lfbinding elements**

The 'lfbinding' element provides a very low-level way to define all model parameter values as well as all input and output maps, time series and tables. The 'lfuser' element is used to define (user-defined) text variables. These text variables can be used to substitute repeatedly used expressions in the binding element. This greatly reduces the amount of work that is needed to prepare the settings file. Each variable is defined as a ‘textvar’ element within ‘lfuser’/‘lfbinding’. Each ‘textvar’ element has the attributes ‘name’ and ‘value’. The following example demonstrates the main principle (note that in the examples below the prolog element is left out, but you will never need to edit this anyway):

```xml
<?xml version="1.0" encoding="UTF-8"?>
<!DOCTYPE lfsettings SYSTEM "lisflood.dtd">

<lfsettings>
  <lfuser>
    <textvar name="PathMaps" value="/c1llx01/floods2/knijfjo/test/maps"/>
  </lfuser>
  <lfoptions/>
  <lfbinding>
    <textvar name="LandUse" value="$(PathMaps)/landuse.map"/>
  </lfbinding>
</lfsettings>
```
In the example two input files (maps) are defined. Both maps are in the same directory. Instead of entering the full file path for every map, we define a variable called \textit{PathMaps} in the 'lfuser' element. This variable can then be used in the 'lfbinding' element. Note that in the 'lfbinding' element you should always wrap user-defined variables in brackets and add a leading dollar sign, e.g. \$\text{(PathMaps)}$. Since the names of the in- and output files are usually the same for each model run, the use of user-defined variables greatly simplifies setting up the model for new catchments. In general, it is a good idea to use user-defined variables for \textit{everything} that needs to be changed on a regular basis (paths to input maps, tables, meteorological data, parameter values). This way you only have to deal with the variables in the 'lfuser' element, without having to worry about anything in 'lfbinding' at all.

Now for a somewhat more realistic example:
From this example, note that anything can be defined with 'lfuser' variables, whether it be paths, file prefixes or parameter value. At first sight it might seem odd to define model parameter like UpperZoneTimeConstant as a text variable when it is already defined in the 'lfbinding' element. However, in practice it is
much easier to have all the important variables defined in the same element: in total the model needs around 200 variables, parameters and file names. By specifying each of those in the 'lfbinding' element you need to specify each of them separately. Using the 'lfuser' variables this can be reduced to about 50, which greatly simplifies things. You should think of the 'lfbinding' element as a low-level way of describing the model in- and output structure: anything can be changed and any file can be in any given location, but the price to pay for this flexibility is that the definition of the input structure will take a lot of work. By using the 'lfuser' variables in a smart way, custom template settings files can be created for specific model applications (calibration, scenario modelling, operational flood forecasting). Typically, each of these applications requires its own input structure, and you can use the 'lfuser' variables to define this structure. Also, note that the both the name and value of each variable must be wrapped in (single or double) quotes. Dedicated XML-editors like XmlSpy take care of this automatically, so you won’t usually have to worry about this.

**NOTES:**

1. It is important to remember that the only function of the 'lfuser' element is to define text variables; you can not use any of these text variables within the 'lfuser' element. For example, the following 'lfuser' element is wrong and will not work:

```xml
<lfuser>
  <textvar name="PathInit" value="/cllx01/floods2/knijfjo/test/init">
    Path to initial conditions maps
  </textvar>
  <textvar name="LZInit" value="$(PathInit)/lzInit.map">
    Initial lower zone storage
    ** USE OF USER VARIABLE WITHIN LFUSER  
    ** IS NOT ALLOWED, SO THIS EXAMPLE WILL NOT WORK!!
  </textvar>
</lfuser>
```

2. It is possible to define everything directly in the 'lfbinding' element without using any text variables at all! In that case the 'lfuser' element can remain empty, even though it has to be present (i.e. `<lfuser> </lfuser>`). In general this is not recommended.

3. Within the lfuser and lfbinding elements, model variables are organised into groups. This is just to make navigation in an xml editor easier.
Variables in the lfbinding element
The variables that are defined in the 'lfbinding' element fall in either of the following categories:

1. Single map

Example:
   <textvar name="LandUse" value="$(PathMaps)/landuse.map">
   <comment>
   Land Use Classes
   </comment>
   </textvar>

2. Table

Example:
   <textvar name="TabKSat1" value="$(PathTables)/ksat1.txt">
   <comment>
   Saturated conductivity [cm/day]
   </comment>
   </textvar>

3. Stack of maps

Example:
   <textvar name="PrecipitationMaps" value="$(PathMeteo)/$(PrefixPrecipitation)">
   <comment>
   precipitation [mm/day]
   </comment>
   </textvar>

Note:
Taking -as an example- a prefix that equals "pr", the name of each map in the stack starts with "pr", and ends with the number of the time step. The name of each map is made up of a total of 11 characters: 8 characters, a dot and a 3-character suffix. For instance:

   pr000000.007 : at time step 7
   pr000035.260 : at time step 35260

To avoid unexpected behaviour, do not use numbers in the prefix! For example:

   <textvar name="PrecipitationMaps" value="$(PathMeteo)/pr10 ">
   <comment>
   precipitation [mm/day]
   </comment>
   </textvar>

For the first time step this yields the following file name:

   pr100000.001

But this is actually interpreted as time step 100,000,001!
4. Time series file

Example:
<textvar name="DisTS" value="$(PathOut)/dis.tss">
    <comment>
        Reported discharge [cu m/s]
    </comment>
</textvar>

5. Single parameter value

Example:
<textvar name="UpperZoneTimeConstant" value="$(UpperZoneTimeConstant)">
    <comment>
        Time constant for water in upper zone [days]
    </comment>
</textvar>

Variables in the Ifuser element
As said before the variables in the 'lfuser' elements are all text variables, and they are used simply to substitute text in the 'lfbinding' element. In practice it is sometimes convenient to use the same name for a text variable that is defined in the 'lfuser' element and a 'lfbinding' variable. For example:

```
<lfuser>
    <textvar name="UpperZoneTimeConstant" value="10">
        <comment>
            Time constant for water in upper zone [days]
        </comment>
    </textvar>
</lfuser>

<lfbinding>
    <textvar name="UpperZoneTimeConstant" value="$(UpperZoneTimeConstant)">
        <comment>
            Time constant for water in upper zone [days]
        </comment>
    </textvar>
</lfbinding>
```

In this case 'UpperZoneTimeConstant' in the 'lfuser' element (just a text variable) is something different from 'UpperZoneTimeConstant' in the 'lfbinding' element!
The ‘lfoption’ element effectively allows you to switch certain parts of the model on or off. Within LISFLOOD, there are two categories of options:

1. Options to activate the reporting of additional output maps and time series (e.g. soil moisture maps)
2. Options that activate special LISFLOOD features, such as inflow hydrographs and the simulation of reservoirs

Viewing available options

You can view all options by running LISFLOOD with the --listoptions flag. For each option, the following information is listed:

<table>
<thead>
<tr>
<th>OptionName</th>
<th>Choices</th>
<th>DefaultValue</th>
</tr>
</thead>
</table>

‘OptionName’ - as you might have guessed already - simply is the name of the option. ‘Choices’ indicates the possible values of the option, and ‘DefaultValue’ describes the default behaviour. For instance, if you look at the reservoir option:

```
simulateReservoirs choices=(1,0) default=0
```

you see that the value of this option is either 0 (off) or 1 (on), and that the default value is 0 (off, i.e. do not simulate any reservoirs).

The information on the reporting options is a little bit different (and slightly confusing). Looking at the option for reporting discharge maps:

```
repDischargeMaps choices=(1) noDefault
```

By default, discharge maps are not reported, so you would expect something like “default=0”. However, due to the way options are defined internally in the model, in this case we have no default value, which means it is switched off. Report options that are switched on by default look like this:

```
repStateMaps choices=(1) default=1
```

To minimise the confusion, you should:

1. Ignore the “Choices” item
2. Interpret “noDefault” as “default=0”

---

4 The reason why --listoptions produces “default=0” for the reservoirs option, is that - internally within the model - the reservoir option consists of two blocks of code: one block is the actual reservoir code, and another one is some dummy code that is activated if the reservoirs option is switched off (the dummy code is needed because some internal model variables that are associated with reservoirs need to be defined, even if no reservoirs are simulated). Both blocks are associated with "simulateReservoirs=1" and "simulateReservoirs=0", respectively, where the "simulateReservoirs=0" block is marked as the default choice. In case of the "repDischargeMaps" option, there is no block of code that is associated with "repDischargeMaps=0", hence formally there is no default value.
This is all a bit confusing, and the displaying of option information may well change in future LISFLOOD versions.

**Defining options**

Within the ‘lfoptions’ element of the settings file, each option is defined using a ‘setoption’ element, which has the attributes ‘name’ and ‘choice’ (i.e. the actual value). For example:

```
<lfoptions>
  <setoption choice="1" name="inflow" />  
</lfoptions>
```

You are not obliged to use any options: if you leave the ‘lfoptions’ element empty, LISFLOOD will simply run using the default values (i.e. run model without optional modules; only report most basic output files). However, the ‘lfoptions’ element itself (i.e. `<lfoptions> </lfoptions>`) has to be present, even if empty!
6. Preparing the settings file

This chapter describes how to prepare your own settings file. Instead of writing the settings file completely from scratch, we suggest to use the settings template that is provided with LISFLOOD as a starting point. In order to use the template, you should make sure the following requirements are met:

- All input maps and tables are named according to default file names (see Chapter 4 and Annex 12)
- All base maps are in the right directories
- All tables are in one directory
- All meteo input is in one directory
- All Leaf Area Index input is in the right directories
- An (empty) directory where all model data can be written exists

If this is all true, the settings file can be prepared very quickly by editing the items in the 'lfuser' element. The following is a detailed description of the different sections of the 'lfuser' element. The present LISFLOOD version contains process-related parameters (not taking into account the parameters that are defined through the maps). These are all defined in the 'lfuser' element, and default values are given for each of them. Even though *any* of these parameters can be treated as calibration constants, doing so for *all* of them would lead to serious over-parameterisation problems. In the description of these parameters we will therefore provide some suggestions as to which parameters should be used for calibration, and which one are better left untouched.

**Time-related constants**

The 'lfuser' section starts with a number of constants that are related to the simulation period and the time interval used. These are all defined as single values.

```xml
<comment>
**************************************************
TIME-RELATED CONSTANTS
**************************************************
</comment>
<textvar name="CalendarDayStart" value="01/01/1990">
Calendar day of 1st day in model run
Day of the year of first map (e.g. xx0.001) even if the model start from map e.g. 500 e.g. 1st of January: 1; 1st of June 151 (or 152 in leap year)
Needed to read out LAI tables correctly
</textvar>
<textvar name="DtSec" value="86400">
timestep [seconds]
</textvar>
<textvar name="DtSecChannel" value="86400">
Sub time step used for kinematic wave channel routing [seconds]
</textvar>
```
Within the model, the smallest out of DtSecChannel and DtSec is used
</comment>
</textvar>

{textvar name="StepStart" value="1"> Number of first time step in simulation
</comment>
</textvar>

{textvar name="StepEnd" value="10"> Number of last time step in simulation
</comment>
</textvar>

{textvar name="ReportSteps" value="endtime"> Time steps at which to write model state maps (i.e. only those maps that would be needed to define initial conditions for succeeding model run)
</comment>
</textvar>

CalendarDayStart is the calendar day of the first map in a map stack e.g. pr000000.001. Even if you start the model from time step 500, this has to be set to the calendar day of the 001 map in your map stacks. Format can be a number: Value="1" = 1st January, Value="151" = 1st June

DtSec is the simulation time interval in seconds. It has a value of 86400 for a daily time interval, 3600 for an hourly interval, etcetera

DtSecChannel is the simulation time interval used by the kinematic wave channel routing (in seconds). Using a value that is smaller than DtSec may result in a better simulation of the overall shape the calculated hydrograph (at the expense of requiring more computing time)

StepStart is the number of the first time step in your simulation. It is normally set to 1. Other (larger) values can be used if you want to run LISFLOOD for only a part of the time period for which you have meteo and LAI maps.

StepEnd is the number of the last time step in your simulation.

ReportSteps defines the time step number(s) at which the model state (i.e. all maps that you would need to define the initial conditions of a succeeding model run) is written. You can define this parameter as a (comma separated) list of time steps. For example:

{textvar name="ReportSteps" value="10,20,40">
will result in state maps being written at time steps 10, 20 and 40. For the last time step of a model run you can use the special 'endtime' keyword, e.g.:

```xml
<textvar name="ReportSteps" value="endtime">
```

Alternatively, in some cases you may need the state maps at regular intervals. In that case you can use the following syntax:

```xml
<textvar name="ReportSteps" value="start+increment..end">
```

For instance, in the following example state maps are written every 5th time step, starting at time step 10, until the last time step:

```xml
<textvar name="ReportSteps" value="10+5..endtime">
```

**Parameters related to evapo(transpiration and interception**

The following parameters are all related to the simulation of evapo(transpiration and rainfall interception. Although they can all be defined as either a single value or as a map, we recommend using the single values that are included in the template. We do not recommend using any of these parameters as calibration constants.

```xml
<comment>
**************************************************************************
PARAMETERS RELATED TO EVAPO(TRANSPIRATION AND INTERCEPTION
**************************************************************************
</comment>

<textvar name="PrScaling" value="1">

Multiplier applied to potential precipitation rates
</textvar>

<textvar name="CalEvaporation" value="1">

Multiplier applied to potential evapo(transpiration rates
</textvar>

<textvar name="LeafDrainageTimeConstant" value="1">

Time constant for water in interception store [days]
</textvar>

<textvar name="kdf" value="0.72">

Average extinction coefficient for the diffuse radiation flux varies with crop from 0.4 to 1.1 (Goudriaan (1977))
</textvar>

<textvar name="AvWaterRateThreshold" value="5">

Critical amount of available water (expressed in [mm/day]!), above which 'Days Since Last Rain' parameter is set to 1
</textvar>

<textvar name="SMaxSealed" value="1.0">

maximum depression storage for water on impervious surface which is not immediatly causing surface runoff [mm]
</textvar>
```
**PrScaling** is a multiplier that is applied to precipitation input (pr) [-]

**CalEvaporation** is a multiplier that is applied to the potential evap(transp)iration input \((ET0, EW0 \text{ and } ES0)\) [-]

**LeafDrainageTimeConstant** \((T_{int} \text{ in Eq 2-11})\) is the time constant for the interception store [days]

**kdf** is the average extinction for the diffuse radiation flux (Goudriaan, 1977). It is used to calculate the extinction coefficient for global radiation, \(\kappa_{gb}\), which is used in Equations 2-9, 2-14 and 2-19 [-]

**AvWaterRateThreshold** defines a critical amount of water that is used as a threshold for resetting the variable \(D_{slr}\) in Eq 2-20. Because the equation was originally developed for daily timesteps only, the threshold is currently defined (somewhat confusingly) as an equivalent intensity in [mm day\(^{-1}\)]

**SMaxSealed** is the maximum depression storage on impervious surface [mm]. This storage is emptied by evaporation (EW0).

**Parameters related to snow and frost**

The following parameters are all related to the simulation of snow accumulation, snowmelt and frost. All these parameters can be defined as either single values or maps. We recommend to start out by leaving them all at their default values. If prior data suggest major under- or overcatch problems in the observed snowfall, **SnowFactor** can be adjusted accordingly. **SnowMeltCoef** may be used as a calibration constant, but since snow observations are typically associated with large uncertainty bands, the calibration may effectively just be compensating for these input errors.
SNOW AND FROST RELATED PARAMETERS

Multiplier applied to precipitation that falls as snow

Range [mm C-1 d-1] of the seasonal variation
SnowMeltCoef is the average value

Snowmelt coefficient [mm/deg C /day]
See also Martinec et al., 1998.

Average temperature at which snow melts

Average temperature below which precipitation is snow

Temperature lapse rate with altitude [deg C / m]

Daily decay coefficient, (Handbook of Hydrology, p. 7.28)

Snow depth reduction coefficient, [cm-1], (HH, p. 7.28)

Snow water equivalent, (based on snow density of 450 kg/m3) (e.g. Tarboton and Luce, 1996)

Degree Days Frost Threshold (stops infiltration, percolation and capillary rise)
Molnau and Bissel found a value 56-85 for NW USA.
SnowFactor is a multiplier that is applied to the rate of precipitation in case the precipitation falls as snow. Since snow is commonly underestimated in meteorological observation data, setting this multiplier to some value greater than 1 can counteract for this [1].

SnowSeasonAdj is the range [mm C-1 d-1] of the seasonal variation of snow melt. SnowMeltCoef is the average value.

SnowMeltCoef (Cm in Eq 2-3) is the degree-day factor that controls the rate of snowmelt [mm °C-1 day-1].

TempMelt (Tm in Eq 2-3) is the average temperature above which snow starts to melt [°C].

TempSnow is the average temperature below which precipitation is assumed to be snow [°C].

TemperatureLapseRate (L in Figure 2.2) is the temperature lapse rate that is used to estimate average temperature at the centroid of each pixel's elevation zones [°C m-1].

Afrost (A in Eq 2-4) is the frost index decay coefficient [day-1]. It has a value in the range 0-1.

Kfrost (K in Eq 2-4) is a snow depth reduction coefficient [cm-1].

SnowWaterEquivalent (we, in Eq 2-4) is the equivalent water depth of a given snow cover, expressed as a fraction [-].

FrostIndexThreshold is the critical value of the frost index (Eq 2-5) above which the soil is considered frozen [°C day-1].

**Infiltration parameters**

The following two parameters control the simulation of infiltration and preferential flow. Both are empirical parameters that are treated as calibration constants, and both can be defined as single values or maps.

---

SnowFactor is a multiplier that is applied to the rate of precipitation in case the precipitation falls as snow. Since snow is commonly underestimated in meteorological observation data, setting this multiplier to some value greater than 1 can counteract for this [1].

SnowSeasonAdj is the range [mm C-1 d-1] of the seasonal variation of snow melt. SnowMeltCoef is the average value.

SnowMeltCoef (Cm in Eq 2-3) is the degree-day factor that controls the rate of snowmelt [mm °C-1 day-1].

TempMelt (Tm in Eq 2-3) is the average temperature above which snow starts to melt [°C].

TempSnow is the average temperature below which precipitation is assumed to be snow [°C].

TemperatureLapseRate (L in Figure 2.2) is the temperature lapse rate that is used to estimate average temperature at the centroid of each pixel's elevation zones [°C m-1].

Afrost (A in Eq 2-4) is the frost index decay coefficient [day-1]. It has a value in the range 0-1.

Kfrost (K in Eq 2-4) is a snow depth reduction coefficient [cm-1].

SnowWaterEquivalent (we, in Eq 2-4) is the equivalent water depth of a given snow cover, expressed as a fraction [-].

FrostIndexThreshold is the critical value of the frost index (Eq 2-5) above which the soil is considered frozen [°C day-1].

**Infiltration parameters**

The following two parameters control the simulation of infiltration and preferential flow. Both are empirical parameters that are treated as calibration constants, and both can be defined as single values or maps.
$b_{Xinanjiang}$ ($b$ in Eq 2-23) is the power in the infiltration equation [-]

$PowerPrefFlow$ ($c_{pref}$ in Eq 2-25) is the power in the preferential flow equation [-]

**Groundwater parameters**

The following parameters control the simulation shallow and deeper groundwater. $GwLossFraction$ should be kept at 0 unless prior information clearly indicates that groundwater is lost beyond the catchment boundaries (or to deep groundwater systems). The other parameters are treated as calibration constants. All these parameters can be defined as single values or maps.

---

**GROUNDWATER RELATED PARAMETERS**

---

- **UpperZoneTimeConstant** ($T_{uz}$ in Eq 2-42) is the time constant for the upper groundwater zone [days]

- **LowerZoneTimeConstant** ($T_{lz}$ in Eq 2-43) is the time constant for the lower groundwater zone [days]

- **GwPercValue** ($GW_{perc}$ in Eq 2-44) is the maximum rate of percolation going from the upper to the lower groundwater zone [mm day$^{-1}$]

---

$GwLoss$ is the maximum rate of percolation from the Lower response box (groundwater loss) [mm/day]. A value of 0 (closed lower boundary) is recommended as a starting value.

---

51
*GwLoss* (\(f_{\text{loss}}\) in Eq 2-45) is the maximum rate of percolation from the lower groundwater zone (groundwater loss) zone [mm day\(^{-1}\)]. A value of 0 (closed lower boundary) is recommended as a starting value.

**Routing parameters**

These parameters are all related to the routing of water in the channels as well as the routing of surface runoff. The multiplier *CalChanMan* can be used to fine-tune the timing of the channel routing, and it may be defined as either a single value or a map. All other parameters should be kept at their default values.

```
<comment>
***************************************************************
ROUTING PARAMETERS
***************************************************************
</comment>

<textvar name="CalChanMan" value="1">
Multiplier applied to Channel Manning's n
</textvar>

<textvar name="beta" value="0.6">
kinematic wave parameter: 0.6 is for broad sheet flow
</textvar>

<textvar name="OFDepRef" value="5">

</textvar>

<textvar name="GradMin" value="0.001">
Minimum slope gradient (for kin. wave: slope cannot be 0)
</textvar>

<textvar name="ChanGradMin" value="0.0001">
Minimum channel gradient (for kin. wave: slope cannot be 0)
</textvar>

*CalChanMan* is a multiplier that is applied to the Manning’s roughness maps of the channel system [-]

*beta* is routing coefficient \(\beta_k\) in Equations 2-51, 2-52, 2-54 and 2-57 [-]

*OFDepRef* is a reference flow depth from which the flow velocity of the surface runoff is calculated [mm]

*GradMin* is a lower limit for the slope gradient used in the calculation of the surface runoff flow velocity [m m\(^{-1}\)]

*ChanGradMin* is a lower limit for the channel gradient used in the calculation of the channel flow velocity [m m\(^{-1}\)]
Parameters related to numerics

This category only contains one parameter at the moment, which can only be a single value. We strongly recommend keeping this parameter at its default value.

---

CourantCrit ($C_{crit}$ in Eq 2-36) is the critical Courant number which controls the numerical accuracy of the simulated soil moisture fluxes [-]. Any value between 0 and 1 can be used, but using values that are too high can lead to unrealistic “jumps” in the simulated soil moisture, whereas very low values result in reduced computational performance (because many iterations will be necessary to obtain the required accuracy). Values above 1 should never be used, as they will result in a loss of mass balance. In most cases the default value of 0.4 results in sufficiently realistic simulations using just a few iterations.

File paths

Here you can specify where all the input files are located, and where output should be written. Note that you can use both forward and backward slashes on both Windows and Linux-based systems without any problem (when LISFLOOD reads the settings file it automatically formats these paths according to the conventions used by the operating system used). The default settings template contains relative paths, which in most cases allows you to run the model directly without changing these settings (assuming that you execute LISFLOOD from the root directory of your catchment).

---
PathOut is the directory where all output files are written. It must be an existing directory (if not you will get an error message – not immediately but after 256 timesteps, when the time series are written for the first time)

PathInit is the directory where the initial files are located, to initialize a "warm" start. It can be also the PathOut directory

PathMaps is the directory where all input base maps are located
PathSoilHyd is the directory where the soil hydraulic property maps are located
PathMapsFraction is the directory where the land cover fraction maps are located
PathMapsTables is the directory where maps are located which were calculated from lookup tables in the previous version (e.g. cropcoeff)

PathTables is the directory where all input tables are located
*PathMeteo* is the directory where all maps with meteorological input are located (rain, evapo(transp)iration, temperature)

*PathLAI* is the directory where you Leaf Area Index maps are located

*PathWaterUse* is the directory where water use maps are located (optional)

**Prefixes of meteo and vegetation related variables**

Here you can define the prefix that is used for each meteorological variable (and LAI and water use).

```xml
<comment>
******************************************************************************
PREFIXES OF METEO AND VEGETATION RELATED VARIABLES
******************************************************************************
</comment>
<textvar name="PrefixPrecipitation" value="pr">
prefix precipitation maps
</textvar>

<textvar name="PrefixTavg" value="ta">
prefix average temperature maps
</textvar>

<textvar name="PrefixE0" value="e">
prefix E0 maps
</textvar>

<textvar name="PrefixES0" value="es">
prefix ES0 maps
</textvar>

<textvar name="PrefixET0" value="et">
prefix ET0 maps
</textvar>

<textvar name="PrefixLAI" value="olai">
prefix LAI maps
</textvar>

<textvar name="PrefixLAIForest" value="flai">
prefix forest LAI maps
</textvar>

<textvar name="PrefixWaterUse" value="wuse">
prefix water use maps
</textvar>
```
Each variable is read as a stack of maps. The name of each map starts with prefix, and ends with the number of the time step. All characters in between are filled with zeroes. The name of each map is made up of a total of 11 characters: 8 characters, a dot and a 3-character suffix. For instance, using a prefix ‘pr’ we get:

- pr000000.007 : at time step 7
- pr000035.260 : at time step 35260

To avoid unexpected behaviour, never use numbers in the prefix! For example:

PrefixRain=pr10

For the first time step this yields the following file name:

pr100000.001

But this is actually interpreted as time step 100,000,001! Therefore, do not use numbers in the prefix!

The corresponding part of the settings file is pretty self-explanatory:

- PrefixPrecipitation is the prefix of the precipitation maps
- PrefixTavg is the prefix of the daily average temperature maps
- PrefixE0 is the prefix of the potential open-water evaporation maps
- PrefixES0 is the prefix of the potential bare-soil evaporation maps
- PrefixET0 is the prefix of the potential (reference) evapotranspiration maps
- PrefixLAI is the prefix of the Leaf Area Index maps
- PrefixLAIForest is the prefix of the forest Leaf Area Index maps
- PrefixWaterUse is the prefix of the water use maps (optional)

**Initial conditions**

As with the calibration parameters you can use both maps and single values to define the catchment conditions at the start of a simulation. Note that a couple of variables can be initialized internally in the model (explained below). Also, be aware that the initial conditions define the state of the model at t=(StepStart -1). As long as StepStart equals 1 this corresponds to t=0, but for larger values of StepStart this is (obviously) not the case!
INITIAL CONDITIONS
/maps or single values

WaterDepthInitValue = 0
initial overland flow water depth [mm]

SnowCoverAInitValue = 0
initial snow depth in snow zone A [mm]

SnowCoverBInitValue = 0
initial snow depth in snow zone B [mm]

SnowCoverCInitValue = 0
initial snow depth in snow zone C [mm]

FrostIndexInitValue = 0
initial Frost Index value

CumIntInitValue = 0
cumulative interception [mm]

UZInitValue = 0
water in upper store [mm]

DSLRInitValue = 1
days since last rainfall

CumIntSealedInitValue = 0
cumulative depression storage [mm]

LZInitValue = -9999
water in lower store [mm]
-9999: use steady-state storage

The following variables can also be initialized in the model internally, if you want this to happen set them to bogus value of -9999

LZInitValue = -9999
water in lower store [mm]
-9999: use steady-state storage
WaterDepthInitValue is the initial amount of water on the soil surface [mm]

SnowCoverInitAValue is the initial snow cover on the soil surface in elevation zone A [mm]

SnowCoverInitBValue is the initial snow cover on the soil surface in elevation zone B [mm]

SnowCoverInitCValue is the initial snow cover on the soil surface in elevation zone C [mm]

FrostIndexInitValue ($F$ in Eq 2-5) initial value of the frost index [$^°C$ day$^{-1}$]

CumIntInitValue is the initial interception storage [mm]

UZInitValue is the initial storage in the upper groundwater zone [mm]

DSLRRInitValue ($D_{slr}$ in Eq 2-20) is the initial number of days since the last rainfall event [days]

CumIntSealedInitValue is the initial value of the depression storage for the sealed part of a pixel [mm]

LZInitValue is the initial storage in the lower groundwater zone [mm]. In order to avoid initialization problems it is possible to let the model calculate a ‘steady state’ storage that will usually minimize any
initialization problems. This feature is described in detail in Chapter 7 of this User Manual. To activate it, set the $\text{lfoptions}$ element $\text{InitLisflood}$ to 1.

$\text{TotalCrossSectionAreaInitValue}$ is the initial cross-sectional area [m$^2$] of the water in the river channels (a substitute for initial discharge, which is directly dependent on this). A value of -9999 sets the initial amount of water in the channel to half bankfull.

$\text{ThetaInit1Value}$ is the initial moisture content [mm$^3$ mm$^{-3}$] of the upper soil layer. A value of -9999 will set the initial soil moisture content to field capacity.

$\text{ThetaInit2Value}$ is the initial moisture content [mm$^3$ mm$^{-3}$] of the lower soil layer. A value of -9999 will set the initial soil moisture content to field capacity.

$\text{PrevDischarge}$ is the initial discharge from previous run [m$^3$s$^{-1}$] used for lakes, reservoirs and transmission loss (only needed if option is on for lakes or reservoirs or transmission loss). Note that $\text{PrevDischarge}$ is discharge as an average over the time step (a flux). A value of -9999 sets the initial amount of discharge to equivalent of half bankfull.

```xml
<comment>
  ************************************************************
  INITIAL CONDITIONS FOREST
  (maps or single values)
  ************************************************************
</comment>
<textvar name="CumIntForestInitValue" value="0">
  cumulative interception [mm]
</textvar>
<textvar name="UZForestInitValue" value="0">
  water in upper store [mm]
</textvar>
<textvar name="DSLRForestInitValue" value="1">
  days since last rainfall
</textvar>
<textvar name="LZForestInitValue" value="-9999">
  water in lower store [mm]
  -9999: use steady-state storage
</textvar>
<textvar name="ThetaForestInit1Value" value="-9999">
  initial soil moisture content layer 1
  -9999: use field capacity values
</textvar>
<textvar name="ThetaForestInit2Value" value="-9999">
  initial soil moisture content layer 2
  -9999: use field capacity values
</textvar>
```
CumIntForestInitValue, UZForestInitValue, DSLRForestInitValue, LZForestInitValue, ThetaForestInit1Value, ThetaForestInit2Value are the initial value for the forest part of a pixel

**Running the model**

To run the model, start up a command prompt (Windows) or a console window (Linux) and type ‘lisflood’ followed by the name of the settings file, e.g.:

`lisflood settings.xml`

If everything goes well you should see something like this:

```
LISFLOOD version March 01 2013 PCR2009W2M095
Water balance and flood simulation model for large catchments

(C) Institute for Environment and Sustainability
Joint Research Centre of the European Commission
TP261, I-21020 Ispra (Va), Italy

Todo report checking within pcrcalc/newcalc
Created: /nahaUsers/burekpe/newVersion/CWstjlDpeO.tmp
pcrcalc version: Mar 22 2011 (linux/x86_64)

Executing timestep 1
```

The LISFLOOD version “March 01 2013 PCR2009W2M095” indicates the date of the source code (01/03/2013), the oldest PCRASTER version it works with (PCR2009), the version of XML wrapper (W2) and the model version (M095).
Using options
As explained in Chapter 5, the ‘lfoptions’ element gives you additional control over what LISFLOOD is doing. Using options it is possible to switch certain parts of the model on or off. This way you can tell the model exactly which output files are reported and which ones aren’t. Also, they can be used to activate a number of additional model features, such as the simulation of reservoirs and inflow hydrographs.

The table in Annex 11 lists all currently implemented options and their corresponding defaults. All currently implemented options are switches (1= on, 0=off). You can set as many options as you want (or none at all). Annex 11 lists all currently implemented options. Note that each option generally requires additional items in the settings file. For instance, using the inflow hydrograph option requires an input map and time series, which have to be specified in the settings file. If you want to report discharge maps at each time step, you will first have to specify under which name they will be written. The template settings file that is provided with LISFLOOD always contains file definitions for all optional output maps and time series. The use of the output options is described in detail in Chapter 8.

Within the ‘lfoptions’ element of the settings file, each option is defined using a ‘setoption’ element, which has the attributes ‘name’ and ‘choice’ (i.e. the actual value). For example:

```xml
<lfoptions>
  <setoption choice="1" name="inflow" />
</lfoptions>
```
7. Initialisation of LISFLOOD

Introduction

Just as any other hydrological model, LISFLOOD needs to have some estimate of the initial state (i.e. amount of water stored) of its internal state variables. Two situations can occur:

1. The initial state of all state variables is known (for example, the “end maps” of a daily water balance run are used to define the initial conditions of an hourly flood-event run)
2. The initial state of all state variables is unknown

The second situation is the most common one, and this chapter presents an in-depth look at the initialisation of LISFLOOD. First the effect of the model’s initial state on the results of a simulation is demonstrated using a simple example. Then, LISFLOOD's various initialisation options are discussed. Most of this chapter focuses on the initialisation of the lower groundwater zone, as this is the model storage component that is the most difficult to initialise.

An example

To better understand the impact of the initial model state on simulation results, let's start with a simple example. Figure 7.1 shows 3 LISFLOOD simulations of soil moisture for the upper soil layer. In the first simulation, it was assumed that the soil is initially completely saturated. In the second one, the soil was assumed to be completely dry (i.e. at residual moisture content). Finally, a third simulation was done where the initial soil moisture content was assumed to be in between these two extremes.
What is clear from the Figure is that the initial amount of moisture in the soil only has a marked effect on the start of each simulation; after a couple of months the three curves converge. In other words, the “memory” of the upper soil layer only goes back a couple of months (or, more precisely, for time lags of more than about 8 months the autocorrelation in time is negligible).

In theory, this behaviour provides a convenient and simple way to initialise a model such as LISFLOOD. Suppose we want to do a simulation of the year 1995. We obviously don’t know the state of the soil at the beginning of that year. However, we can get around this by starting the simulation a bit earlier than 1995, say one year. In that case we use the year 1994 as a warm-up period, assuming that by the start of 1995 the influence of the initial conditions (i.e. 1-1-1994) is negligible. The very same technique can be applied to initialise LISFLOOD’s other state variables, such as the amounts of water in the lower soil layer, the upper groundwater zone, the lower groundwater zone, and in the channel.

**Setting up a LISFLOOD run (cold start)**

When setting up a model run that includes a warm-up period, most of the internal state variables can be simply set to 0 at the start of the run. This applies to the initial amount of water on the soil surface (WaterDepthInitValue), snow cover (SnowCoverInitValue), frost index (FrostIndexInitValue), interception storage (CumIntInitValue), and storage in the upper groundwater zone (UZInitValue). The initial value of the ‘days since last rainfall event’ (DslrInitValue) is typically set to 1.

---

**Figure 7.1** Simulation of soil moisture in upper soil layer for a soil that is initially at saturation (s), at residual moisture content (r) and in between ((s+r)/2)
For the remaining state variables, initialisation is somewhat less straightforward. The amount of water in the channel (defined by `TotalCrossSectionAreaInitValue`) is highly spatially variable (and limited by the channel geometry). The amount of water that can be stored in the upper and lower soil layers (`ThetaInit1Value`, `ThetaInit2Value`) is limited by the soil’s porosity. The lower groundwater zone poses special problems because of its overall slow response (discussed in a separate section below). Because of this, LISFLOOD provides the possibility to initialise these variables internally, and these special initialisation methods can be activated by setting the initial values of each of these variables to a special ‘bogus’ value of -9999. Table 7.1 summarises these special initialisation methods:

<table>
<thead>
<tr>
<th>Variable</th>
<th>Description</th>
<th>Initialisation method</th>
</tr>
</thead>
<tbody>
<tr>
<td>ThetaInit1Value / ThetaForestInit2Value</td>
<td>initial soil moisture content upper soil layer (V/V)</td>
<td>set to soil moisture content at field capacity</td>
</tr>
<tr>
<td>ThetaInit2Value / ThetaForestInit2Value</td>
<td>initial soil moisture content lower soil layer (V/V)</td>

1) These special initialisation methods are activated by setting the value of each respective variable to a ‘bogus’ value of -9999.

Note that the “-9999” ‘bogus’ value can only be used with the variables in Table 7.1; for all other variables they will produce nonsense results! The initialisation of the lower groundwater zone will be discussed in the next sections.

**Initialisation of the lower groundwater zone**

Even though the use of a sufficiently long warm-up period usually results in a correct initialisation, a complicating factor is that the time needed to initialise any storage component of the model is dependent on the average residence time of the water in it. For example, the moisture content of the upper soil layer tends to respond almost instantly to LISFLOOD’s meteorological forcing variables (precipitation, evapo(transpi)ration). As a result, relatively short warm-up periods are sufficient to initialise this storage component. At the other extreme, the response of the lower groundwater zone is generally very slow (especially for large values of $T_{lz}$). Consequently, to avoid unrealistic trends in the simulations, very long warm-up periods may be needed. Figure 7.2 shows a typical example for an 8-year simulation, in which a decreasing trend in the lower groundwater zone is visible throughout the whole simulation period.

Because the amount of water in the lower zone is directly proportional to the baseflow in the channel, this will obviously lead to an unrealistic long-term simulation of baseflow. Assuming the long-term climatic input is more or less constant, the baseflow (and thus the storage in the lower zone) should be free of any long-term trends (although some seasonal variation is normal). In order to
avoid the need for excessive warm-up periods, LISFLOOD is capable of calculating a ‘steady-state’ storage amount for the lower groundwater zone. This steady state storage is very effective for reducing the lower zone’s warm-up time. In the next sections the concept of steady state is first explained, and it is shown how it can be used to speed up the initialisation of a LISFLOOD run.

Lower groundwater zone: steady state storage

The response of the lower groundwater zone is defined by two simple equations. First, we have the inflow into the lower zone, which occurs at the following rate [mm day\(^{-1}\)]:

\[
D_{uz,lz} = \min(GW_{perc}, UZ / \Delta t)
\]  

(7-1)

Here, \(GW_{perc} [\text{mm day}^{-1}]\) is a user-defined value (calibration constant), and \(UZ\) is the amount of water available in the upper groundwater zone [mm]. The rate of flow out of the lower zone [mm day\(^{-1}\)] equals:

\[
Q_{lz} = \frac{1}{T_{lz}} \cdot LZ
\]  

(7-2)

where \(T_{lz}\) is a reservoir constant [days], and \(LZ\) is the amount of water that is stored in the lower zone [mm].

Now, let’s do a simple numerical experiment: assuming that \(D_{uz,lz}\) is a constant value, we can take some arbitrary initial value for \(LZ\) and then simulate (e.g. in a
spreadsheet) the development over LZ over time. Figure 7.3 shows the results of 2 such experiments. In the upper Figure, we start with a very high initial storage (1500 mm). The inflow rate is fairly small (0.2 mm/day), and $T_{lz}$ is quite small as well (which means a relatively short residence time of the water in the lower zone). What is interesting here is that, over time, the storage evolves asymptotically towards a constant state. In the lower Figure, we start with a much smaller initial storage (50 mm), but the inflow rate is much higher here (1.5 mm/day) and so is $T_{lz}$ (1000 days). Here we see an upward trend, again towards a constant value. However, in this case the constant 'end' value is not reached within the simulation period, which is mainly because $T_{lz}$ is set to a value for which the response is very slow.

At this point it should be clear that what you see in these graphs is exactly the same behaviour that is also apparent in the ‘real’ LISFLOOD simulation in Figure 7.2. Being able to know the ‘end’ storages in Figure 7.3 in advance would be very helpful, because it would eliminate any trends. As it happens, this can be done very easily from the model equations. A storage that is constant over time means that the in- and outflow terms balance each other out. This is known as a steady state situation, and the constant ‘end’ storage is in fact the steady state storage. The rate of change of the lower zone’s storage at any moment is given by the continuity equation:

$$\frac{dLZ}{dt} = I(t) - O(t) \quad (7-3)$$

where $I$ is the (time dependent) inflow (i.e. groundwater recharge) and $O$ is the outflow rate. For a situation where the storage remains constant, we can write:

$$\frac{dLZ}{dt} = 0 \quad \Leftrightarrow \quad I(t) - O(t) = 0 \quad (7-4)$$
Figure 7.3 Two 10-year simulations of lower zone storage with constant inflow.
Upper Figure: high initial storage, storage approaches steady-state storage (dashed) after about 1500 days. Lower Figure: low initial storage, storage doesn’t reach steady-state within 10 years.

This equation can be re-written as:

\[ I(t) - \frac{1}{T_{lz}} \cdot LZ = 0 \]  

(7-5)
Solving this for $LZ$ gives the steady state storage:

$$LZ_{ss} = T_{lz} \cdot I(t) \quad (7-6)$$

We can check this for our numerical examples:

<table>
<thead>
<tr>
<th>$T_{lz}$</th>
<th>$I$</th>
<th>$LZ_{ss}$</th>
</tr>
</thead>
<tbody>
<tr>
<td>250</td>
<td>0.2</td>
<td>50</td>
</tr>
<tr>
<td>1000</td>
<td>1.5</td>
<td>1500</td>
</tr>
</tbody>
</table>

which corresponds exactly to the results of Figure 7.3.

**Steady-state storage in practice**

An actual LISFLOOD simulation differs from the previous example in 2 ways. First, in any real simulation the inflow into the lower zone is not constant, but varies in time. This is not really a problem, since $LZ_{ss}$ can be computed from the average recharge. However, this is something we do not know until the end of the simulation! Also, the inflow into the lower zone is controlled by the availability of water in the upper zone, which, in turn, depends on the supply of water from the soil. Hence, it is influenced by any calibration parameters that control behaviour of soil- and subsoil (e.g. $T_{uz}$, $GW_{perc}$, $b$, and so on). This means that when calibrating the model, the average recharge will be different for every parameter set. Note, however, that it will always be smaller than the value of $GW_{perc}$, which is used as an upper limit in the model. Note that the pre-run procedures include a sufficiently long warm-up period.

**Use pre-run to calculate average recharge**

Here, we first do a “pre-run” that is used to calculate the average inflow into the lower zone. This average inflow can be reported as a map, which is then used in the actual run. This involves the following steps:

1. Set all the initial conditions to either 0, 1 or -9999
2. Activate the “InitLisflood” option by setting it active in the ‘lfoptions’ in the settings file:

   ```xml
   <setoption choice="1" name="InitLisflood"/>
   ```

3. Run the model for a longer period (if possible more than 3 years, best for the whole modelling period)
4. Go back to the LISFLOOD settings file, and set the `InitLisflood` inactive:

   ```xml
   <setoption choice="0" name="InitLisflood"/>
   ```

5. Run the model again using the modified settings file
In this case, the initial state of \( LZ \) is computed for the correct average inflow, and the simulated storage in the lower zone throughout the simulation should not show any systematic (long-term) trends. The obvious price to pay for this is that the pre-run increase the computational load. However the pre-run will use a simplified routing to decrease the computational run-time. As long as the simulation period for the actual run and the pre-run are identical, the procedure gives a 100% guarantee that the development of the lower zone storage will be free of any systematic bias. Since the computed recharge values are dependent on the model parameterisation used, in a calibration setting the whole procedure must be repeated for each parameter set!

**Checking the lower zone initialisation**

The presence of any initialisation problems of the lower zone can be checked by adding the following line to the ‘lfoptions’ element of the settings file:

```xml
<setoption name="repStateUpsGauges" choice="1"></setoption>
```

This tells the model to write the values of all state variables (averages, upstream of contributing area to each gauge) to time series files. The default name of the lower zone time series is ‘lzUps.tss’. Figure 7.4 shows an example of an 8-year simulation that was done both without (dashed line) and with a pre-run. The simulation without the pre-run shows a steady decreasing trend throughout the 8-year period, whereas the simulation for which the pre-run was used doesn’t show this long-term trend (although in this specific case a modest increasing trend is visible throughout the first 6 years of the simulation, but this is related to trends in the meteorological input).

![Figure 7.4 Initialisation of lower groundwater zone with and without using a pre-run. Note the strong decreasing trend in the simulation without pre-run.](image)

70
Using a previous run (warm start)

At the end of each model run, LISFLOOD writes maps of all internal state variables at the last time step. You can use these maps as the initial conditions for a succeeding simulation. This is particularly useful if you are simulating individual flood events on a small time interval (e.g. hourly). For instance, to estimate the initial conditions just before the flood you can do a ‘pre-run’ on a daily time interval for the year before the flood. You can then use the ‘end maps’ as the initial conditions for the hourly simulation.

In any case, you should be aware that values of some internal state variables of the model (especially lower zone storage) are very much dependent on the parameterisation used. Hence, suppose we have ‘end maps’ that were created using some parameterisation of the model (let’s say parameter set A), then these maps should not be used as initial conditions for a model run with another parameterisation (parameter set B). If you decide to do this anyway, you are likely to encounter serious initialisation problems (but these may not be immediately visible in the output!). If you do this while calibrating the model (i.e. parameter set B is the calibration set), this will render the calibration exercise pretty much useless (since the output is the result of a mix of different parameter sets). However, for FrostIndexInitValue and DSLRInitValue it is perfectly safe to use the ‘end maps’, since the values of these maps do not depend on any calibration parameters (that is, only if you do not calibrate on any of the frost-related parameters!). If you need to calibrate for individual events (i.e. hourly), you should apply each parameterisation on both the (daily) pre-run and the ‘event’ run! This may seem awkward, but there is no way of getting around this (except from avoiding event-based calibration at all, which may be a good idea anyway).

Summary of LISFLOOD initialisation procedure

From the foregoing it is clear that the initialisation of LISFLOOD can be done in a number of ways. Figure 7.5 gives an overview. As already stated in the introduction section, any LISFLOOD simulation will fall into either of the following two categories:

1. The initial state of all state variables is known and defined by the end state of a previous run. In this case you can use the ‘end’ maps of the previous run’s state variables as the initial conditions of your current run. Note that this requires that both simulations are run using exactly the same parameter set! Mixing parameter sets here will introduce unwanted artefacts into your simulation results.
2. The initial state of all state variables is unknown. In this case you should run the model with a sufficient pre-run (if possible more than 3 years, best for the whole modelling period) and InitLisflood=1. The average recharge map that is generated from the pre-run can subsequently be used as the average lower zone inflow estimate (LZAvInflowEstimate) in the actual simulation, which will avoid any initialisation problems of the lower groundwater zone.
3. Is it possible not to use the first year for further analysis of results, because this is the “warm-up” period for all the other variables like snow, vegetation, soil (see e.g. figure 7.1 for soil moisture)? Then leave or set all the initial conditions to either 0, 1 or -9999 and run the model with InitLisflood=0.

4. If you want to include the first year of modelling into your analysis, you have to do a “warm-up” run (one year will usually do) to initialize all the initial conditions. You have to set option repEndMaps=1 to report end maps. Best possible solution is to use the year before the actual modelling period. Second best is to use any one year period to set up the initial conditions. After that you will have the ‘end’ maps and you can proceed with 1. again.

Figure 7.5 LISFLOOD initialisation flowchart
8. Output generated by LISFLOOD

Default LISFLOOD output

LISFLOOD can generate a wide variety of output. Output is generated as either maps or time series (PCRaster format, which can be visualised with PCRaster’s ‘aguila’ application). Reporting of output files can be switched on and off using options in the LISFLOOD settings file. Also, a number of output files are specific to other optional modules, such as the simulation of reservoirs. The following table lists all the output time series that are reported by default (note that the file names can always be changed by the user, although this is not recommended):

<table>
<thead>
<tr>
<th>Table 8.1 LISFLOOD default output time series</th>
</tr>
</thead>
<tbody>
<tr>
<td>RATE VARIABLES AT GAUGES</td>
</tr>
<tr>
<td>Description</td>
</tr>
<tr>
<td>1. channel discharge</td>
</tr>
<tr>
<td>2. cumulative mass balance error</td>
</tr>
<tr>
<td>2. cumulative mass balance error, expressed as mm water slice (average over catchment)</td>
</tr>
<tr>
<td>2. number of sub-steps needed for channel routing</td>
</tr>
<tr>
<td>2. number of sub-steps needed for gravity-based soil moisture routine</td>
</tr>
<tr>
<td>1. Output only if option ‘InitLisflood’ = 1 (pre-run)</td>
</tr>
<tr>
<td>2. Output only if option ‘InitLisflood’ = 0</td>
</tr>
</tbody>
</table>

To speed up the pre-run and to prevent that results are taken from the pre-run, all additional output is disabled if option ‘InitLisflood’ = 1 is chosen. With ‘InitLisflood’ = 1 the output is limited to dis.tss, lzavin.map, lzavin_forest.map and some other initial maps if additional option like e.g. the double kinematic wave is chosen.

In addition to these time series, by default LISFLOOD reports maps of all state variables at the last timestep of a simulation. These maps can be used to define the initial conditions of a succeeding simulation. For instance, you can do a 1-year simulation on a daily time step, and use the ‘end maps’ of this simulation to simulate a flood event using an hourly time step. Table 8.2 and Annex 13 list all these maps. Note that some state variables are valid for the whole pixel, whereas others are only valid for a sub-domain of each pixel. This is indicated in the last column of the table.

---

5 Can be disabled by either option repStateMaps=0 or setting ReportSteps to a high value e.g. <textvar name="ReportSteps" value="99999">

1. Output only if option ‘InitLisflood’ = 1 (pre-run)
2. Output only if option ‘InitLisflood’ = 0

Additional output

Apart from the default output, the model can –optionally- generate some additional time series and maps. Roughly this additional output falls in either of the following categories:

Time series
1. Time series with values of model state variables at user-defined locations (sites); reporting of these time series can be activated using the option repStateSites=1. Note that ‘sites’ can be either individual pixels or larger areas (e.g. catchments, administrative areas, and so on). In case of larger areas the model reports the average value for each respective area.

6 Output time steps are defined with ReportSteps in the settings file (see chapter 5) or only for the last time step with option ‘repEndMaps’
7 xxx represents the number of the last time step; e.g. or a 730-step simulation the end map of ‘waterdepth’ will be ‘wdepth00.730’, and so on.
2. Time series with values of model rate variables at user-defined locations (sites); reporting of these time series can be activated using the option 
   \textit{repRateSites}=1

3. Time series with values of meteorological input variables, averaged over the area upstream of each gauge location; reporting of these time series can be activated using the option \textit{repMeteoUpsGauges}=1

4. Time series with values of model state variables, averaged over area upstream of each gauge location; reporting of these time series can be activated using the option \textit{repStateUpsGauges}=1

5. Time series with values of model rate variables, averaged over area upstream of each gauge location; reporting of these time series can be activated using the option \textit{repRateUpsGauges}=1

6. Time series that are specific to other options (e.g. simulation of reservoirs).

Maps
1. Maps of discharge at each time step; reporting of these maps can be activated using the option \textit{repDischargeMaps}=1
2. Maps with values of driving meteorological values at each time step
3. Maps with values of model rate variables at each time step
4. Maps that are specific to other options (e.g. simulation of reservoirs).

In addition, some additional maps and time series may be reported for debugging purposes. In general these are not of any interest to the LISFLOOD user, so they remain undocumented here.

Note that the options \textit{repStateUpsGauges}, \textit{repRateUpsGauges} and \textit{repDischargeMaps} tend to slow down the execution of the model quite dramatically. For applications of the model where performance is critical (e.g. automated calibration runs), we advise to keep them switched off, if possible.

The additional time series are listed in the Annex 13. Note again the domains for which variables are valid: all rate variables are reported as pixel-average values. Soil moisture and groundwater storage are reported for the permeable fraction of each pixel only. The reported snow cover is the average of the snow depths in snow zones A, B and C.

By default, the names of the reported discharge maps start with the prefix ‘\textit{dis}’ and end with the time step number (the naming conventions are identical to the ones used for the input maps with meteorological variables, which is explained in Chapter 4). Annex 13 summarises all options to report additional output maps. The previous remarks related to the domains for which the state variable values are valid also apply to the maps listed in Annex 13.

Annex 1: Simulation of reservoirs

Introduction
This annex describes the LISFLOOD reservoirs routine, and how it is used. The simulation of reservoirs is optional, and it can be activated by adding the following line to the 'lfoptions' element:

```
<setoption name="simulateReservoirs" choice="1" />
```

Reservoirs can be simulated on channel pixels where kinematic wave routing is used. The routine does not work for channel stretches where the dynamic wave is used!

Description of the reservoir routine
Reservoirs are simulated as points in the channel network. The inflow into each reservoir equals the channel flow upstream of the reservoir. The outflow behaviour is described by a number of parameters. First, each reservoir has a total storage capacity $S$ [m$^3$]. The relative filling of a reservoir, $F$, is a fraction between 0 and 1. There are three 'special' filling levels. First, each reservoir has a 'dead storage' fraction, since reservoirs never empty completely. The corresponding filling fraction is the 'conservative storage limit', $L_c$. For safety reasons a reservoir is never filled to the full storage capacity. The 'flood storage limit' ($L_f$) represents this maximum allowed storage fraction. The buffering capacity of a reservoir is the storage available between the 'flood storage limit' and the 'normal storage limit' ($L_n$). Three additional parameters define the way the outflow of a reservoir is regulated. For e.g. ecological reasons each reservoir has a 'minimum outflow' ($O_{min}$ [m$^3$ s$^{-1}$]). For high discharge situations, the 'non-damaging outflow' ($O_{nd}$ [m$^3$ s$^{-1}$]) is the maximum possible outflow that will not cause problems downstream. The 'normal outflow' ($O_{norm}$ [m$^3$ s$^{-1}$]) is valid once the reservoir reaches its 'normal storage' filling level.

Depending on the relative filling of the reservoir, outflow ($O_{res}$ [m$^3$ s$^{-1}$]) is calculated as:

$$O_{res} = \min(O_{min}, \frac{1}{\Delta t} F \cdot S) \quad \text{for } F \leq 2L_c$$

$$O_{res} = O_{min} + (O_{norm} - O_{min}) \frac{(F - 2L_c)}{(L_n - 2L_c)} \quad \text{for } L_n \geq F > 2L_c$$

$$O_{res} = O_{norm} + \frac{(F - L_n)}{(L_f - L_n)} \cdot \max\{(I_{res} - O_{norm}), (O_{nd} - O_{norm})\} \quad \text{for } L_f \geq F > L_n$$

$$O_{res} = \max\left(\frac{(F - L_f)}{\Delta t}, S, O_{nd}\right) \quad \text{for } F > L_f$$
where:

\( S \) : Reservoir storage capacity [m\(^3\)]
\( F \) : Reservoir fill (fraction, 1 at total storage capacity) [-]
\( L_c \) : Conservative storage limit [-]
\( L_n \) : Normal storage limit [-]
\( L_f \) : Flood storage limit [-]
\( O_{\text{min}} \) : Minimum outflow [m\(^3\) s\(^{-1}\)]
\( O_{\text{norm}} \) : Normal outflow [m\(^3\) s\(^{-1}\)]
\( O_{\text{nd}} \) : Non-damaging outflow [m\(^3\) s\(^{-1}\)]
\( I_{\text{res}} \) : Reservoir inflow [m\(^3\) s\(^{-1}\)]

In order to prevent numerical problems, the reservoir outflow is calculated using a user-defined time interval (or \( \Delta t \), if it is smaller than this value).

**Preparation of input data**

For the simulation of reservoirs a number of additional input files are necessary. First, the locations of the reservoirs are defined on a (nominal) map called ‘res.map’. It is important that all reservoirs are located on a channel pixel (you can verify this by displaying the reservoirs map on top of the channel map). Also, since each reservoir receives its inflow from its upstream neighbouring channel pixel, you may want to check if each reservoir has any upstream channel pixels at all (if not, the reservoir will gradually empty during a model run!). The management of the reservoirs is described by 7 tables. The following table lists all required input:

</tbody>
</table>

When you create the map with the reservoir sites, pay special attention to the following: if a reservoir is on the most downstream cell (i.e. the outflow point, see Figure A1.1), the reservoir routine may produce erroneous output. In particular, the mass balance errors cannot be calculated correctly in that case. The same applies if you simulate only a sub-catchment of a larger map (by selecting the subcatchment in the mask map). This situation can usually be avoided by extending the mask map by one cell in downstream direction.
Figure A1.1 Placement of the reservoirs: reservoirs on the outflow point (left) result in erroneous behavior of the reservoir routine.

**Preparation of settings file**

All in- and output files need to be defined in the settings file. If you are using a default LISFLOOD settings template, all file definitions are already defined in the ‘lfbinding’ element. Just make sure that the map with the reservoir locations is in the “maps” directory, and all tables in the ‘tables’ directory. If this is the case, you only have to specify the time-step used for the reservoir calculations and the initial reservoir filling level (expressed as a fraction of the storage capacity). Both are defined in the ‘lfuser’ element of the settings file. For the reservoir time step ($Dt_{SecReservoirs}$) it is recommended to start with a value of 14400 (4 hours), and try smaller values if the simulated reservoir outflow shows large oscillations. $ReservoirInitialFillValue$ can be either a map or a value (between 0 and 1). So we add this to the ‘lfuser’ element (if it is not there already):

```xml
<group>
  <comment>
  **************************************************************
  RESERVOIR OPTION
  **************************************************************
  </comment>
  <textvar name="DtSecReservoirs" value="14400">
    <comment>
      Sub time step used for reservoir simulation [s]. Within the model, the smallest out of DtSecReservoirs and DtSec is used.
    </comment>
  </textvar>
  <textvar name="ReservoirInitialFillValue" value="-9999">
    <comment>
      Initial reservoir fill fraction
      -9999 sets initial fill to normal storage limit
      if you’re not using the reservoir option, enter some bogus value
    </comment>
  </textvar>
</group>
```

The value -9999 tells the model to set the initial reservoir fill to the normal storage limit. Note that this value is completely arbitrary. However, if no other information is available this may be a reasonable starting point.
Finally, you have to tell LISFLOOD that you want to simulate reservoirs! To do this, add the following statement to the 'lfoptions' element:

```xml
<setoption name="simulateReservoirs" choice="1" />
```

Now you are ready to run the model. If you want to compare the model results both with and without the inclusion of reservoirs, you can switch off the simulation of reservoirs either by:

1. Removing the 'simulateReservoirs' statement from the 'lfoptions element,
   or
2. changing it into `<setoption name="simulateReservoirs" choice="0" />

Both have exactly the same effect. You don’t need to change anything in either 'lfuser' or 'lfbinding'; all file definitions here are simply ignored during the execution of the model.

To report the ReservoirFillState the option:

```xml
<setoption name="repsimulateReservoirs" choice="1"/>
```

has to be put in or set to 1.

**Reservoir output files**

The reservoir routine produces 3 additional time series and one map, as listed in the following table:

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>ReservoirFillState</td>
<td>rsfilxxx.xxx</td>
<td>reservoir fill at last time step 8</td>
<td>-</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Time series</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>ReservoirInflowTS</td>
<td>qresin.tss</td>
<td>inflow into reservoirs</td>
<td>m³/s</td>
<td></td>
</tr>
<tr>
<td>ReservoirOutflowTS</td>
<td>qresout.tss</td>
<td>outflow out of reservoirs</td>
<td>m³/s</td>
<td></td>
</tr>
<tr>
<td>ReservoirFillTS</td>
<td>resfill.tss</td>
<td>reservoir fill</td>
<td>-</td>
<td></td>
</tr>
</tbody>
</table>

Note that you can use the map with the reservoir fill at the last time step to define the initial conditions of a succeeding simulation, e.g.:

```xml
<textvar name="ReservoirInitialFillValue" value="/mycatchment/rsfil000.730"/>
```

---

8: xxx represents the number of the last time step; e.g. for a 730-step simulation the name will be 'rsfil000.730', and so on.
Annex 2: Polder option

Introduction
This annex describes the LISFLOOD polder routine, and how it is used. The simulation of polders is optional, and it can be activated by adding the following line to the 'lfoptions' element:

```xml
<setoption name="simulatePolders" choice="1" />
```

Polders can be simulated on channel pixels where dynamic wave routing is used. The routine does not work for channel stretches where the kinematic wave is used!

Description of the polder routine
Polders are simulated as points in the channel network. The polder routine is adapted from Förster et. al (2004), and based on the weir equation of Poleni (Bollrich & Preisler, 1992). The flow rates from the channel to the polder area and vice versa are calculated by balancing out the water levels in the channel and in the polder, as shown in Figure A2.1.

![Figure A2.1 Schematic overview of the simulation of polders. pb is the polder bottom level (above the channel bottom); wc is the water level in the channel; hc and hp are the water levels above the polder in-/outflow, respectively.](image)

From the Figure, it is easy to see that there can be three situations:

1. \( h_c > h_p \): water flows out of the channel, into the polder. The flow rate, \( q_{c,p} \), is calculated using:

\[
q_{c,p} = \mu c b \sqrt{2g h_c^{3/2}};
\]

\[
c = \left( 1 - \frac{h_p}{h_c} \right)^{16}
\]  

(A2.1)
where \( b \) is the outflow width [m], \( g \) is the acceleration due to gravity (9.81 m s\(^{-2}\)) and \( \mu \) is a weir constant which has a value of 0.49. Furthermore \( q_{c,p} \) is in [m\(^3\) s\(^{-1}\)].

2. \( h_c < h_p \): water flows out of the polder back into the channel. The flow rate, \( q_{p,o} \), is now calculated using:

\[
q_{p,c} = \mu c b \sqrt{2 g h_p^{3/2}}; \\
c = \sqrt{1 - \left(\frac{h_c}{h_p}\right)^{16}}
\]  

(A2.2)

3. \( h_c = h_p \): no water flowing into either direction (note here that the minimum value of \( h_c \) is zero). In this case both \( q_{c,p} \) and \( q_{p,c} \) are zero.

**Regulated and unregulated polders**

The above equations are valid for unregulated polders. It is also possible to simulate regulated polders, which is illustrated in Figure A2.2. Regulated polders are opened at a user-defined time (typically during the rising limb of a flood peak). The polder closes automatically once it is full. Subsequently, the polder is opened again to release the stored water back into the channel, which also occurs at a user-defined time. The opening- and release times for each polder are defined in two lookup tables (see Table 2.1). In order to simulate the polders in unregulated mode these times should both be set to a bogus value of -9999. Only if both opening- and release time are set to some other value, LISFLOOD will simulate a polder in regulated mode. Since LISFLOOD only supports one single regulated open-close-release cycle per simulation, you should use regulated mode only for single flood events. For continuous simulations (e.g. long-term waterbalance runs) you should only run the polders in unregulated mode.
Figure A2.2 Simulation of a regulated polder. Polder is closed (inactive) until user-defined opening time, after which it fills up to its capacity (flow rate according to Eq A2.1). Water stays in polder until user-defined release time, after which water is released back to the channel (flow rate according to Eq A2.2).

Preparation of input data

The locations of the reservoirs are defined on a (nominal) map called ‘polders.map’. Any polders that are not on a channel pixel are ignored by LISFLOOD, so you may want to check the polder locations before running the model (you can do this by displaying the reservoirs map on top of the channel map). The current implementation of the polder routine may result in numerical instabilities for kinematic wave pixels, so for the moment it is recommended to define polders only on channels where the dynamic wave is used. Furthermore, the properties of each polder are described using a number of tables. All required input is listed in the following table:
Table A.2.1  Input requirements polder routine

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>PolderSites</td>
<td>polders.map</td>
<td>polder locations</td>
<td>-</td>
<td>nominal</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Tables</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>TabPolderArea</td>
<td>poldarea.txt</td>
<td>polder area</td>
<td>m²</td>
<td></td>
</tr>
<tr>
<td>TabPolderOFWidth</td>
<td>poldofw.txt</td>
<td>polder in- and outflow width</td>
<td>m</td>
<td></td>
</tr>
<tr>
<td>TabPolderTotalCapacity</td>
<td>poldcap.txt</td>
<td>polder storage capacity</td>
<td>m³</td>
<td></td>
</tr>
<tr>
<td>TabPolderBottomLevel</td>
<td>poldblevel.txt</td>
<td>Bottom level of polder, measured from channel bottom level (see also Figure A4.1)</td>
<td>m</td>
<td></td>
</tr>
<tr>
<td>TabPolderOpeningTime</td>
<td>poldtopen.txt</td>
<td>Time at which polder is opened</td>
<td>time step</td>
<td></td>
</tr>
<tr>
<td>TabPolderReleaseTime</td>
<td>poldtrelease.txt</td>
<td>Time at which water stored in polder is released again</td>
<td>time step</td>
<td></td>
</tr>
</tbody>
</table>

Note that the polder opening- and release times are both defined a time step numbers (not days or hours!!). For unregulated polders, set both parameters to a bogus value of -9999, i.e.:

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>10</td>
<td>-9999</td>
</tr>
<tr>
<td>15</td>
<td>-9999</td>
</tr>
<tr>
<td>16</td>
<td>-9999</td>
</tr>
<tr>
<td>17</td>
<td>-9999</td>
</tr>
</tbody>
</table>

Preparation of settings file

All in- and output files need to be defined in the settings file. If you are using a default LISFLOOD settings template, all file definitions are already defined in the ‘lfbinding’ element. Just make sure that the map with the polder locations is in the “maps” directory, and all tables in the ‘tables” directory. If this is the case, you only have to specify the initial reservoir water level in the polders. *PolderInitialLevelValue* is defined in the ‘lfuser’ element of the settings file, and it can be either a map or a value. The value of the weir constant \( \mu \) is also defined here, although you should not change its default value. So we add this to the ‘lfuser’ element (if it is not there already):
To switch on the polder routine, add the following line to the ‘lfoptions’ element:

```xml
<setoption name="simulatePolders" choice="1"/>
```

Now you are ready to run the model. If you want to compare the model results both with and without the inclusion of polders, you can switch off the simulation of polders either by:

3. Removing the ‘simulatePolders’ statement from the ‘lfoptions’ element, or
4. changing it into `<setoption name="simulatePolders" choice="0"/>`

Both have exactly the same effect. You don’t need to change anything in either ‘lfuser’ or ‘lfbinding’; all file definitions here are simply ignored during the execution of the model.

**Polder output files**

The polder routine produces 2 additional time series and one map (or stack of maps, depending on the value of LISFLOOD variable `ReportSteps`), as listed in the following table:
### Table A2.2 Output of polder routine

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>PolderLevelState</td>
<td>hpolxxxx.xxx</td>
<td>water level in polder at last time step(^9)</td>
<td>m</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Time series</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>PolderLevelTS</td>
<td>hPolder.tss</td>
<td>water level in polder (at polder locations)</td>
<td>m</td>
<td></td>
</tr>
<tr>
<td>PolderFluxTS</td>
<td>qPolder.tss</td>
<td>Flux into and out of polder (positive for flow from channel to polder, negative for flow from polder to channel)</td>
<td>m(^3)/s</td>
<td></td>
</tr>
</tbody>
</table>

Note that you can use the map with the polder level at the last time step to define the initial conditions of a succeeding simulation, e.g.:

<textvar name="PolderInitialLevelValue" value="/mycatchment/hpol0000.730"/>

### Limitations

For the moment, polders can be simulated on channel pixels where dynamic wave routing is used. For channels where the kinematic wave is used, the routine will not work and may lead to numerical instabilities or even model crashes. This limitation may be resolved in future model versions.

\(^{9}\) xxx represents the number of the last time step; e.g. for a 730-step simulation the name will be ‘hpol0000.730’, and so on.
Annex 3: Simulation of lakes

Introduction
This annex describes the LISFLOOD lake routine, and how it is used. The simulation of lakes is optional, and it can be activated by adding the following line to the 'lfoptions' element:

<setoption name="simulateLakes" choice="1" />

Lakes can be simulated on channel pixels where kinematic wave routing is used. The routine does not work for channel stretches where the dynamic wave is used!

Description of the lake routine
Lakes are simulated as points in the channel network. Figure A3.1 shows all computed in- and outgoing fluxes. Lake inflow equals the channel flow upstream of the lake location. Lake evaporation occurs at the potential evaporation rate of an open water surface.

Figure A3.1 Schematic overview of the simulation of lakes. $H_0$ is the water level at which the outflow is zero; $H$ is the water level in the lake and EW is the evaporation from the lake
Lake retention can be seen as special case of flood retention with horizontal water level. Therefore the basic equations of channel routing (equations 2-48 to 2-54 pages 23-24) can be written as:

\[
\frac{(Q_{in1} + Q_{in2})}{2} - \frac{(Q_{out1} + Q_{out2})}{2} = \frac{(S_2 + S_1)}{\Delta t}
\]  

(A3.1)

Where:
- \(Q_{in1}\): Inflow to lake at time 1 (t)
- \(Q_{in2}\): Inflow to lake at time 2 (t+\(\Delta t\))
- \(Q_{out1}\): Outflow from lake at time 1 (t)
- \(Q_{out2}\): Outflow from lake at time 2 (t+\(\Delta t\))
- \(S_1\): Lake storage at time 1 (t)
- \(S_2\): Lake Storage at time 2 (t+\(\Delta t\))

Simply stated, the change in storage is equal to inflow minus outflow. To solve this equation you need to know the lake storage curve \(S=f(h)\) and the rating curve \(Q=f(h)\). Lake storage and discharge have to be linked to each other by the water level (see fig A3.2).

\[Q = \alpha \cdot H^2\]

\[S = A \cdot H\]

Figure A3.2 Relation between sea level, lake outflow and lake storage

**Modified Puls Approach** (see also Maniak, 1997):

The modified Puls approach avoids iteration steps to solve the equation A3.1 by reforming the equation to:

\[
\frac{S_2}{\Delta t} + \frac{Q_{out2}}{2} = \left(S_1 + \frac{Q_{out1}}{2}\right) - Q_{out1} + \frac{(Q_{in1} + Q_{in2})}{2}
\]

(A3.2)

The right part of this equation can be solved because \(S_1\), \(Q_{out1}\) and \(Q_{in1}\) is given from the previous timestep and \(Q_{in2}\) is the inflow to the lake at the current timestep.

\[
SI = \left(S_1 + \frac{Q_{out1}}{2}\right) - Q_{out1} + \frac{(Q_{in1} + Q_{in2})}{2}
\]

(A3.3)
For the left part two assumptions are made here to simplify and fasten the modified Puls approach:

1. The outflow of the lake is based on a modification of the weir equation of Poleni (Bollrich & Preißler, 1992)

\[ Q = \mu \cdot b \cdot \sqrt{2g} \cdot H^{\frac{1}{2}} = \alpha \cdot H^{\frac{1}{2}} \] (Poleni weir equation for rectangular weir)

Assuming the weir is not rectangular but is a parabola we can simplify this to:

\[ Q = \alpha \cdot H^2 \]

where: \( Q \): outflow discharge; \( H \): sea level;
\( \alpha \): parameter of channel width, gravity and weir coefficient

2. The best approach for a sea level vs. lake storage function would be a lookup table. For a simplified approach a linear relation is assumed:

\[ S = A \cdot H \]

where: \( S \): lake storage; \( A \): lake area; \( H \): sea level

Therefore:

\[ SI = S_2 \cdot \frac{Q_{out2}}{2} + \frac{A \cdot H}{\Delta t} + \frac{Q_{out2}}{2} = \frac{A \cdot \sqrt{Q_{out2}}}{\Delta t \cdot \sqrt{\alpha}} + \frac{Q_{out2}}{2} \] (A3.4)

Replacing: \( H = \sqrt{\frac{Q_{out2}}{\alpha}} \)

Equation A3.4 can be solved as quadratic equation for \( Q_{out2} \).

\[ Q_{out2} = \left( -\text{LakeFactor} + \sqrt{\text{LakeFactor}^2 + 2 \cdot SI} \right)^2 \] (A3.5)

Where:

LakeFactor: \[ \frac{A}{\Delta t \cdot \sqrt{\alpha}} \]
SI: equation A3.3

**Initialisation of the lake routine**

Because lakes (especially large ones) tend to produce a relatively slow response over time, it is important to make sure that the initial lake level is set to a more or less sensible value. LISFLOOD has two options for the initial value:

1. If a “LakeInitialLevelValue” is given as a value or a map from a previous run, this is taken an initial lake level.
2. If “LakeInitialLevelValue” is set to -9999 the initial lake level will be calculated from a steady-state net-lake inflow [m³/s]. The steady-state net-lake inflow is given by a table called TabLakeAvNetInflowEstimate
In this table the average net inflow \((Q - EW)\) is listed. The average net inflow can be estimated using measured discharge and evaporation records. If measured discharge is available just downstream of the lake (i.e. the outflow), the (long-term) average outflow can be used as the net inflow estimate (since, for a steady state situation, inflow equals outflow). If only inflow is available, all average inflows should be summed, and the average lake evaporation should be subtracted from this figure. Table A3.1 gives a worked example. Be aware that the calculation can be less straightforward for very large lakes with multiple inlets.

**Table A3.1: Calculation of average net lake inflow**

<table>
<thead>
<tr>
<th><strong>Lake characteristics</strong></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>lake area:</td>
<td>(215 \times 10^6) m(^2)</td>
</tr>
<tr>
<td>mean annual discharge downstream of lake:</td>
<td>(293) m(^3) s(^{-1})</td>
</tr>
<tr>
<td>mean annual discharge upstream of lake:</td>
<td>(300) m(^3) s(^{-1})</td>
</tr>
<tr>
<td>mean annual evaporation:</td>
<td>(1100) mm yr(^{-1})</td>
</tr>
</tbody>
</table>

**Calculation of average net inflow**

**METHOD 1: USING AVERAGE OUTFLOW**

assuming lake is in quasi steady-state:

\[
\text{average net inflow} = \text{average net outflow} = 293 \text{ m}^3 \text{s}^{-1}
\]

**METHOD 2: USING AVERAGE INFLOW AND EVAPORATION**

Only use this method if no outflow data are available

1. **Express lake evaporation in m\(^3\) s\(^{-1}\):**

   \[
   1100 \text{ mm yr}^{-1} / 1000 = 1.1 \text{ m yr}^{-1}
   
   1.1 \text{ m yr}^{-1} \times 215 \times 10^6 \text{ m}^2 = 2.37 \times 10^8 \text{ m}^3 \text{ yr}^{-1}
   
   2.37 \times 10^8 \text{ m}^3 \text{ yr}^{-1} / (365 \text{ days} \times 86400 \text{ seconds}) = 7.5 \text{ m}^3 \text{ s}^{-1}
   
2. **Compute net inflow:**

\[
\text{net inflow} = 300 \text{ m}^3 \text{s}^{-1} - 7.5 \text{ m}^3 \text{s}^{-1} = 292.5 \text{ m}^3 \text{s}^{-1}
\]

**Preparation of input data**

The lake locations defined on a (nominal) map called ‘lakes.map’. It is important that all reservoirs are located on a channel pixel (you can verify this by displaying the reservoirs map on top of the channel map). Also, since each lake receives its inflow from its upstream neighbouring channel pixel, you may want to check if each lake has any upstream channel pixels at all (if not, the lake will just gradually empty during a model run). The lake characteristics are described by 3 tables. Table 3.2 lists all required input.
When you create the map with the lake locations, pay special attention to the following: if a lake is located on the most downstream cell (i.e. the outflow point, see Figure A3.3), the lake routine may produce erroneous output. In particular, the mass balance errors cannot be calculated correctly in that case. The same applies if you simulate only a sub-catchment of a larger map (by selecting the subcatchment in the mask map). This situation can usually be avoided by extending the mask map by one cell in downstream direction.

<table>
<thead>
<tr>
<th>Table A3.2 Input requirements lake routine</th>
</tr>
</thead>
<tbody>
<tr>
<td>Maps</td>
</tr>
<tr>
<td>Default name</td>
</tr>
<tr>
<td>LakeSites</td>
</tr>
<tr>
<td>Tables</td>
</tr>
<tr>

</tr>
<tr>
<td>TabLakeA</td>
</tr>
<tr>
<td>TabLakeAvNetInflowEstimate</td>
</tr>
</tbody>
</table>

**Figure A3.3** Placement of the lakes: lakes on the outflow point (left) result in erroneous behavior of the lake routine.

**Preparation of settings file**

All in- and output files need to be defined in the settings file. If you are using a default LISFLOOD settings template, all file definitions are already defined in the ‘lfbinding’ element. Just make sure that the map with the lake locations is in the “maps” directory, and all tables in the ‘tables” directory. If this is the case, you only have to specify the initial lake level and – if you are using the steady-state option- the mean net lake inflow (make this a map if you’re simulating multiple lakes simultaneously). Both can be set in the ‘lfuser’ element. 

LakeInitialLevelValue can be either a map or a single value. Setting LakeInitialLevelValue to -9999 will cause LISFLOOD to calculate the steady-state level. So we add this to the ‘lfuser’ element (if it is not there already):
LAKE OPTION

Initial lake level [m]
-9999 sets initial value to steady-state level

Estimate of average net inflow into lake (=inflow - evaporation) [cu m / s]
Used to calculated steady-state lake level in case LakeInitialLevelValue is set to -9999

In the <lfbinding> section of the setting file:

LAKE SITES

Map with location of lakes

Initial lake level [m]
-9999 sets initial value to steady-state level

Estimate of average net inflow into lake (=inflow - evaporation) [cu m / s]
Used to calculated steady-state lake level in case LakeInitialLevelValue is set to -9999

Input tables

Lake surface area [sq m]

Lake parameter A
Finally, you have to tell LISFLOOD that you want to simulate lakes! To do this, add the following statement to the ‘lfoptions’ element:

```xml
<setoption name="simulateLakes" choice="1" />
```

Now you are ready to run the model. If you want to compare the model results both with and without the inclusion of lakes, you can switch off the simulation of lakes either by:

5. Removing the ‘simulateLakes’ statement from the ‘lfoptions’ element, or
6. changing it into `<setoption name="simulateLakes" choice="0" />`

Both have exactly the same effect. You don’t need to change anything in either ‘lfuser’ or ‘lfbinding’; all file definitions here are simply ignored during the execution of the model.

To report the LakeLevelState the option

```xml
<setoption name="repsimulateLakes" choice="1" />
```

has to be put in or set to 1.
**Lake output files**

The lake routine produces 4 additional time series and one map (or stack), as listed in the following table:

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>LakeLevelState</td>
<td>lakhxxxx.xxx</td>
<td>lake level at last time step(^{10})</td>
<td>m</td>
<td>repsimulate Lakes = 1</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Time series</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>LakeInflowTS</td>
<td>qLakeIn.tss</td>
<td>inflow into lakes</td>
<td>m(^3)/s</td>
<td></td>
</tr>
<tr>
<td>LakeOutflowTS</td>
<td>qLakeOut.tss</td>
<td>flow out of lakes</td>
<td>m(^3)/s</td>
<td></td>
</tr>
<tr>
<td>LakeEWTS</td>
<td>EWLake.tss</td>
<td>lake evaporation</td>
<td>mm</td>
<td></td>
</tr>
<tr>
<td>LakeLevelTS</td>
<td>hLake.tss</td>
<td>lake level</td>
<td>m</td>
<td></td>
</tr>
</tbody>
</table>

Note that you can use the map with the lake level at the last time step to define the initial conditions of a succeeding simulation, e.g.:

<textvar name="LakeInitialLevelValue" value="/mycatchment/lakh0000.730"/>

\(^{10}\) xxx represents the number of the last time step; e.g. for a 730-step simulation the name will be 'lakh0000.730', and so on.
Annex 4: Inflow hydrograph option

Introduction
This annex describes the LISFLOOD inflow hydrograph routine, and how it is used. Inflow hydrographs are optional, and can be activated by adding the following line to the 'Ifoptions' element:

```xml
<setoption name="inflow" choice="1"/>
```

Description of the inflow hydrograph routine
When using the inflow hydrograph option, time series of discharge \([\text{m}^3/\text{s}]\) are added at some user-defined location(s) on the channel network. The inflow is added as side-flow in the channel routing equations (this works for both kinematic and dynamic wave). Negative inflows (i.e. outflows) are also possible, but large outflow rates may sometimes result in numerical problems in the routing equations. If you use a negative inflow rate, we advise to carefully inspect the model output for any signs of numerical problems (i.e. strange oscillations in simulated discharge, generation of missing values). Also check the mass balance time series after your simulation (numerical problems often result in unusually large mass balance errors).

Using inflow hydrographs
The table below lists the input requirements for the inflow hydrograph option. All you need is a map that defines where you want to add the inflow, and a time series with the corresponding inflow rates.

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>InflowPoints</td>
<td></td>
<td>locations for inflow hydrographs</td>
<td></td>
<td>nominal</td>
</tr>
</tbody>
</table>

Using the inflow hydrograph option involves four steps:

1. Create a (nominal) PCRaster map with unique identifiers that point to the location(s) where you want to insert the inflow hydrograph(s)

2. Save the inflow hydrograph(s) in PCRaster time series format; inflow hydrographs need to be given in \([\text{m}^3 \text{ s}^{-1}]\)
IMPORTANT: PCRaster assumes that the first data series in the time series file (i.e. the second column, since the first column contains the time step number) corresponds to unique identifier 1 on the InflowPoints map; the second series to unique identifier 2, and so on. So, even if your InflowPoints map only contains (as an example) identifiers 3 and 4, you still need to include the columns for identifiers 1 and 2!! The best thing to do in such a case is to fill any unused columns with zeroes (0). Also, your inflow hydrograph time series should always start at $t=1$, even if you set StepStart to some higher value. For more info on time series files please have a look at the PCRaster documentation.

3. Make sure that the names of the map and time series are defined in the settings file

In the 'lfuser' element (replace the file paths/names by the ones you want to use):

```
<group>
  <comment>
  ***************************************************************
  INFLOW HYDROGRAPH (OPTIONAL)
  ***************************************************************
  </comment>
  <textvar name="InflowPoints" value="/floods2/yourhomedir/yourcatchment/maps/inlets.map">
    <comment>
      OPTIONAL: nominal map with locations of (measured) inflow hydrographs [cu m / s]
    </comment>
  </textvar>
  <textvar name="QInTS" value="/floods2/yourhomedir/yourcatchment/inflow/inflow.tss">
    <comment>
      OPTIONAL: observed or simulated input hydrographs as time series [cu m / s]
    </comment>
  </textvar>
</group>
```

4. Activate the inflow hydrograph option

Add the following line to the 'lfoptions' element:

```
<setoption name="inflow" choice="1" />
```

Now you are ready to run the model with the inflow hydrograph.
Substituting subcatchments with measured inflow hydrographs

One of the most common uses of the inflow hydrograph option is this: suppose we have a catchment where we only want to simulate the downstream part. If measured time series of discharge are available for the upstream catchment(s), we can use these to represent the inflow into the more downstream part. Figure A4.1 shows an example, where we have measured discharge of subcatchment A (just before it enters the main river). In this case it is important to pay special attention to two issues.

Exclude subcatchments from MaskMap

First, make sure that subcatchment A is excluded (i.e. have boolean(0) or missing value) on LISFLOOD’s MaskMap (which defines which pixels are included in the calculations and which are not). If you include it, LISFLOOD will first simulate discharge coming out of subcatchment A, and then add the (measured) inflow on top of it! Of course this doesn’t make any sense, so always be careful which areas are included in your simulation and which are not.

Figure A4.1 Using the inflow hydrograph using measured discharge of subcatchment A. MaskMap must have boolean(0) (or missing value) for subcatchment A, see text for explanation.
Make sure your inflow points are where you need them
If you already have all gauge locations on a PCRaster map, these mostly cannot be used directly as inflow hydrograph locations. The reason is simple: suppose – in our previous example – we know the outflow point of subcatchment A. This point is the most downstream point within that subcatchment. However, the flow out of subcatchment A is actually added to the main river one cell downstream! Also, if we exclude subcatchment A from our simulation (as explained in the foregoing), this means we also exclude the outflow point of that subcatchment. Because of this, inflow points into the main river are usually located one pixel downstream of the outflow points of the corresponding subcatchment. If you already have a (nominal) map of your subcatchments, a PCRaster script exists that automatically calculates the corresponding out- and inflow points.
Annex 5: Double kinematic wave option

Introduction
This annex describes the LISFLOOD double kinematic wave routine, and how it is used. Double kinematic wave routing is optional, and can be activated by adding the following line to the ‘lfoptions’ element:

<setoption name="SplitRouting" choice="1" />

Background
The flow routing is done by the kinematic wave approach. Therefore two equations have to be solved:

\[
\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = q \\
\rho g A (S_0 - S_f) = 0 \\
\]

continuity equation  momentum equation as expressed by Chow et al. 1988

Which decreasing inflow the peaks of the resulting outflow will be later in time (see figure A5.1 for a simple kinematic wave calculation). The wave propagation slows down because of more friction on the boundaries.

![Figure A5.1 Simulated outflow for different amount of inflow wave propagation gets slower](image)

This is realistic if your channel looks like in figure A5.2:

![Figure A5.2 Schematic cross section of a channel with different water level](image)
But a natural channel looks more like this:

![Figure A5.3 Schematic cross section of a natural channel](image)

Which means, opposite to the kinematic wave theory, the wave propagation gets slower as the discharge is increasing, because friction is going up on floodplains with shrubs, trees, bridges. Some of the water is even stored in the floodplains (e.g. retention areas, seepage retention). As a result of this, a single kinematic wave cannot cover these different characteristics of floods and floodplains.

**Double kinematic wave approach**

The double kinematic approach splits up the channel in two parts (see figure A5.4):

1. bankful routing
2. over bankful routing

![Figure A5.4 Channel is split in a bankful and over bankful routing](image)

Similar methods are used since the 1970s e.g. as multiple linear or non linear storage cascade (Chow, 1988). The former forecasting model for the River Elbe (ELBA) used a three stages approach depending on discharge (Fröhlich, 1996).
Using double kinematic wave

No additional maps or tables are needed for initializing the double kinematic wave. A normal run (`InitLisflood`=0) requires an additional map derived from the prerun (`InitLisflood`=1). A ‘warm’ start (using initial values from a previous run) requires two additional maps with state variables for the second (over ‘bankful’ routing).

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>Average discharge</td>
<td>avgdis.map</td>
<td>Average discharge</td>
<td>m³/s</td>
<td>Produced by prerun</td>
</tr>
<tr>
<td>CrossSection2Area InitValue</td>
<td>ch2cr000.xxx</td>
<td>channel crosssection for 2nd routing channel</td>
<td>m²</td>
<td>Produced by option ’repStateMaps’ or ’repEndMaps’</td>
</tr>
<tr>
<td>PrevSideflowInitValue</td>
<td>chside00.xxx</td>
<td>sideflow into the channel</td>
<td>mm</td>
<td></td>
</tr>
</tbody>
</table>

Using the double kinematic wave approach option involves three steps:

1. In the ‘lfuser’ element (replace the file paths/names by the ones you want to use):

   ```xml
   <textvar name="CalChanMan2" value="8.5">
   <comment>
   Channel Manning's n for second line of routing
   </comment>
   </textvar>

   ```

   *CalChanMan2* is a multiplier that is applied to the Manning's roughness maps of the over bankful routing [-]

   ```xml
   <textvar name="QSplitMult" value="2.0">
   <comment>
   Multiplier applied to average Q to split into a second line of routing
   </comment>
   </textvar>

   ```

   *QSplitMult* is a factor to the average discharge to determine the bankful discharge. The average discharge map is produced in the initial run (the initial run is already needed to get the groundwater storage). Standard is set to 2.0 (assuming over bankful discharge starts at 2.0-average discharge).

2. Activate the split routing option
   Add the following line to the 'lfoptions' element:

   ```xml
   <setoption name="SplitRouting" choice="1" />
   ```
3. Run LISFLOOD first with

```xml
<setoption name="InitLisflood" choice="1"/>
```

and it will produce a map of average discharge [m³/s] in the initial folder. This map is used together with the QSplitMult factor to set the value for the second line of routing to start.

For a 'warm start' these initial values are needed (see also table A5.1)

```xml
<textvar name="CrossSection2AreaInitValue" value="-9999">  
  initial channel crosssection for 2nd routing channel
  -9999: use 0
</textvar>

<textvar name="PrevSideflowInitValue" value="-9999">  
  initial sideflow for 2nd routing channel
  -9999: use 0
</textvar>
```

*CrossSection2AreaInitValue* is the initial cross-sectional area [m^2] of the water in the river channels (a substitute for initial discharge, which is directly dependent on this). A value of -9999 sets the initial amount of water in the channel to 0.

*PrevSideflowInitValue* is the initial inflow from each pixel to the channel [mm]. A value of -9999 sets the initial amount of sideflow to the channel to 0.
Annex 6: Dynamic wave option

Introduction
This annex describes the LISFLOOD dynamic wave routine, and how it is used. The current implementation of the dynamic wave function in PCRaster is not a complete dynamic wave formulation according to the summary of the Saint Venant equations as discussed in Chow (1988). The implementation currently consists of the friction force term, the gravity force term and the pressure force term and should therefore be correctly characterised as a diffusion wave formulation. The equations are solved as an explicit, finite forward difference scheme. A straightforward iteration using an Euler solution scheme is used to solve these equations. Dynamic wave routing is optional, and can be activated by adding the following line to the 'lfoptions' element:

<setoption name="dynamicWave" choice="1" />

Time step selection
The current dynamic wave implementation requires that all equations are solved using a time step that is much smaller (order of magnitude: seconds-minutes) than the typical overall time step used by LISFLOOD (order of magnitude: hours-day). More specifically, during one (sub) time step no water should be allowed to travel more than 1 cell downstream, i.e.:

\[ \Delta t_{dyn} \leq \frac{\Delta x}{V + c_d} \]

where \(\Delta t_{dyn}\) is the sub-step for the dynamic wave [seconds], \(\Delta x\) is the length of one channel element (pixel) [m], \(V\) is the flow velocity [m s\(^{-1}\)] and \(c_d\) is dynamic wave celerity [m s\(^{-1}\)]. The dynamic wave celerity can be calculated as (Chow, 1988):

\[ c_d = \sqrt{gy} \]

where \(g\) is the acceleration by gravity [m s\(^{-2}\)] and \(y\) is the depth of flow [m]. For a cross-section of a regular geometric shape, \(y\) can be calculated from the channel dimensions. Since the current dynamic wave routine uses irregularly shaped cross-section data, we simply assume that \(y\) equals the water level above the channel bed. The flow velocity is simply:

\[ V = \frac{Q_{ch}}{A} \]

where \(Q_{ch}\) is the discharge in the channel [m\(^3\) s\(^{-1}\)], and \(A\) the cross-sectional area [m\(^2\)].

The Courant number for the dynamic wave, \(C_{dyn}\) can now be computed as:
\begin{equation}
C_{dyn} = \frac{(V + c_d) \Delta t}{\Delta x}
\end{equation}

where $\Delta t$ is the overall model time step [s]. The number of sub-steps is then given by:

\begin{equation}
SubSteps = \max(1, \text{roundup}(\frac{C_{dyn}}{C_{dyn, crit}}))
\end{equation}

where $C_{dyn, crit}$ is the critical Courant number. The maximum value of the critical Courant number is 1; in practice it is safer to use a somewhat smaller value (although if you make it too small the model becomes excessively slow). It is recommended to stick to the default value (0.4) that is used the settings file template.

**Input data**

A number of additional input files are necessary to use the dynamic wave option. First, the channel stretches for which the dynamic wave is to be used are defined on a Boolean map. Next, a cross-section identifier map is needed that links the (dynamic wave) channel pixels to the cross-section table (see further on). A channel bottom level map describes the bottom level of the channel (relative to sea level). Finally, a cross-section table describes the relationship between water height ($H$), channel cross-sectional area ($A$) and wetted perimeter ($P$) for a succession of $H$ levels.

The following table lists all required input:

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>ChannelsDynamic</td>
<td>chandyn.map</td>
<td>dynamic wave channels (1,0)</td>

</tr>
</tbody>
</table>
Layout of the cross-section parameter table

The cross-section parameter table is a text file that contains – for each cross-section - a sequence of water levels ($H$) with their corresponding cross-sectional area ($A$) and wetted perimeter ($P$). The format of each line is as follows:

<table>
<thead>
<tr>
<th>ID</th>
<th>$H$</th>
<th>$A$</th>
<th>$P$</th>
</tr>
</thead>
<tbody>
<tr>
<td>167</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>167</td>
<td>1.507</td>
<td>103.044</td>
<td>114.183</td>
</tr>
<tr>
<td>167</td>
<td>3.015</td>
<td>362.28</td>
<td>302.652</td>
</tr>
<tr>
<td>167</td>
<td>4.522</td>
<td>902.288</td>
<td>448.206</td>
</tr>
<tr>
<td>167</td>
<td>6.03</td>
<td>1709.097</td>
<td>600.382</td>
</tr>
<tr>
<td>167</td>
<td>6.217</td>
<td>1821.849</td>
<td>609.433</td>
</tr>
<tr>
<td>167</td>
<td>6.591</td>
<td>2049.726</td>
<td>615.835</td>
</tr>
<tr>
<td>167</td>
<td>6.778</td>
<td>2164.351</td>
<td>618.012</td>
</tr>
<tr>
<td>167</td>
<td>6.965</td>
<td>2279.355</td>
<td>620.14</td>
</tr>
<tr>
<td>167</td>
<td>7.152</td>
<td>2395.037</td>
<td>626.183</td>
</tr>
<tr>
<td>167</td>
<td>7.713</td>
<td>2746.569</td>
<td>634.07</td>
</tr>
<tr>
<td>167</td>
<td>7.9</td>
<td>2864.589</td>
<td>636.93</td>
</tr>
<tr>
<td>167</td>
<td>307.9</td>
<td>192201.4874</td>
<td>5225.1652</td>
</tr>
</tbody>
</table>

As an example:

Note here that the first $H$-level is always 0, for which $A$ and $P$ are (of course) 0 as well. For the last line for each cross-section it is recommended to use some very (i.e. unrealistically) high $H$-level. The reason for doing this is that the dynamic wave routine will crash if during a simulation a water level (or cross-sectional area) is simulated which is beyond the range of the table. This can occur due to a number of reasons (e.g. if the measured cross-section is incomplete, or during calibration of the model). To estimate the corresponding values of $A$ and $P$ one could for example calculate $dA/dH$ and $dP/dH$ over the last two ‘real’ (i.e. measured) $H$-levels, and extrapolate the results to a very high $H$-level.

The number of $H/A/P$ combinations that are used for each cross section is user-defined. LISFLOOD automatically interpolates in between the table values.
**Using the dynamic wave**

The 'lfuser' element contains two parameters that can be set by the user: *CourantDynamicCrit* (which should always be smaller than 1) and a parameter called *DynWaveConstantHeadBoundary*, which defines the boundary condition at the most downstream cell. All remaining dynamic-wave related input is defined in the 'lfbinding' element, and doesn't require any changes from the user (provided that all default names are used, all maps are in the standard 'maps' directory and the profile table is in the 'tables' directory). In 'lfuser' this will look like this:

```xml
<comment>
**************************************************************
DYNAMIC WAVE OPTION
**************************************************************
</comment>
<textvar name="CourantDynamicCrit" value="0.5">
Critical Courant number for dynamic wave
value between 0-1 (smaller values result in greater numerical accuracy,
but also increase computational time)
</textvar>
<comment>
DynWaveConstantHeadBoundary
Constant head [m] at most downstream pixel (relative to altitude
at most downstream pixel)
</comment>
</textvar>
```
Annex 7: Using the transmission loss option

Introduction

This annex describes the LISFLOOD transmission loss routine, and how it is used. The term ‘transmission loss’ originate from electronic or communication science and stands for: “The loss of power or voltage of a transmitted wave or current in passing along a transmission line or path or through a circuit device”. In river systems, particularly in semi-arid and arid region a similar effect can be observed: The loss of water along channel reaches mainly especially during low and average flow periods. Main reasons for this loss might be:

- Evaporation of water inside the channel reach
- Use of water for domestic, industrial or agricultural use
- Leaching to lower groundwater zones

A simplified approach to model this effect has been chosen from Rao and Maurer (1996), without the need of additional data and with only three parameters, making calibration relatively simple.

Transmission loss is optional, and can be activated by adding the following line to the 'lfoptions' element:

```xml
<setoption name="TransLoss" choice="1" />
```

Description of the transmission loss approach

The approach by Rao and Maurer 1996 builds a one-parameter relationship between the seepage of a channel with the depth of flow. A power relationship is then utilized for the stage-discharge relationship, which is coupled with the seepage relationship.

\[
Outflow = \left( \frac{1}{Inflow^{TransPower} - TransSub} \right)^{TransPower}
\]

with:  
- Outflow: discharge at the outflow  
- Inflow: discharge at the Inflow (upstream)  
- TransPower: Parameter given by the rating curve  
- TransSub: Parameter which is to calibrate

As a main difference to the Rao and Maurer 1996, the TransPower parameter is not calculated by using a rating curve but is estimated (calibrated) as the parameter TransSub. Transmission loss takes place where the channel gets bigger with more influence of river-aquifer interaction and also with more river-floodplain interaction. Therefore a minimum upstream area is defined where transmission loss starts to get important.
**Using transmission loss**

No additional maps or tables are needed. Using the transmission loss option involves two steps:

1. In the ‘lfuser’ element (replace the file paths/names by the ones you want to use):

```xml
<group>
    <comment>
        ************************************************************
        TRANSMISSION LOSS PARAMETERS
        ************************************************************
        Suggested parameterisation strategy:
        Use TransSub as calibration constant leave all other parameters at default values
    </comment>

    <textvar name="TransSub" value="0.3">
        Transmission loss function parameter
        Standard: 0.3 Range: 0.1 - 0.6
    </textvar>

    <textvar name="TransPower1" value="2.0">
        Transmission loss function parameter
        Standard: 2.0 Range 1.3 - 2.0
    </textvar>

    <textvar name="TransArea" value="5.0E+10">
        Downstream area taking into account for transmission loss
        Standard: 5.0E+10 Range: 1.0E+10 - 1.0E+11
    </textvar>

</group>
```

*TransSub* is the linear transmission loss parameter. Standard is set to 0.3 and the range should be between 0.1 - 0.6 (higher values lead to more loss)

*TransPower* is the power transmission loss parameter. Standard is set to 2.0 and the range should be between 1.3 and 2.0 (higher values lead to more loss)

*TransArea* is the downstream area which is taken into account for transmission loss. Standard is 5.0E+10 km² and range should be 1.0E+10 km² to 1.0E+11 km² (higher values lead to less loss as less area is taken into account)
2. Activate the transmission loss option
   Add the following line to the 'ifoptions' element:

   ```xml
   <setoption name="TransLoss" choice="1" />
   ```

   Now you are ready to run the model with the transmission loss option

   **Transmission loss output file**

   The transmission option can produce an additional time series as listed in the following table:

<table>
<thead>
<tr>
<th>Time series</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
</tr>
</thead>
<tbody>
<tr>
<td>TransLossAvUps</td>
<td>TransLossAvUps.tss</td>
<td>Transmission loss in the channel</td>
<td>mm</td>
</tr>
</tbody>
</table>
Annex 8: Including water use

Introduction
This annex describes the LISFLOOD water use routine, and how it is used. The water use routine can be used to assess the effect of water withdrawal from different sectors to the water balance. Sectors can be public, industrial, agricultural or energy water withdrawal. As input LISFLOOD needs a stack of maps for one representative year of total water withdrawal demand. According to the available water LISFLOOD calculates if this demand can be fulfilled and removes the possible amount of withdrawal water from the river system. Water use is optional, and can be activated by adding the following line to the ‘lfoptions’ element:

```
<setoption name="wateruse" choice="1" />
```

Calculation of water use
The water is withdrawn only from discharge in the river network but not from soil, groundwater or directly from precipitation.
- For each single day a total demand of withdrawal water is loaded from a sparse stack of maps
- Water use is taken from the discharge in the river network. First the water use is taken from the same grid cell (see figure A8.1 – pixel No. 1)
- If the amount of water withdrawal is larger than the water available in this grid cell water is taken from downstream moving along the local drain direction. This is done by implementing a loop subtracting the remaining water from the next downstream cell till all the water for water use is taken or a predefined number of iteration is reached (see figure A8.1 – pixel No. 2 to 5)

![Figure A8.1 Water withdrawal assessing demand and availability along the flow path](image)

In the settings.xml you can define:
- the percentage of water that must remain in a grid cell and is not withdrawn by water use (WUsePercRemain)
- the maximum number of loops (= distance to the water demand cell). For example in figure 8.1: \( \text{maxNoWateruse} = 5 \)

**Preparation of input data**

Table A8.1 gives an overview about the maps and table needed for the water use option.

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
</tr>
</thead>
<tbody>
<tr>
<td>Yearly stack of water use maps</td>
<td>wuse0000.xxx</td>
<td>Total water withdrawal</td>
<td>m(^3/s)</td>
</tr>
<tr>
<td>Optional: water region map</td>
<td>Waterregion.map</td>
<td>Nominal map with water regions in maps folder Only if useWaterregions = 1</td>
<td>-</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Table</th>
<th>Default name</th>
<th>Description</th>
<th>Units</th>
</tr>
</thead>
<tbody>
<tr>
<td>WUseofDay</td>
<td>WUseofDays.txt</td>
<td>Assignment of day of the year to map stack of water use</td>
<td>-</td>
</tr>
</tbody>
</table>

A sparse map stack of one year of total water withdrawal [m\(^3/s\)] with a map every 10 days or a month is needed. Because it is assumed that water use follows a yearly circle, this map stack is used again and again for the following years. For example:

<table>
<thead>
<tr>
<th>t</th>
<th>map name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>wuse0000.001</td>
</tr>
<tr>
<td>2</td>
<td>wuse0000.032</td>
</tr>
<tr>
<td>3</td>
<td>wuse0000.060</td>
</tr>
<tr>
<td>4</td>
<td>wuse0000.091</td>
</tr>
<tr>
<td>5</td>
<td>wuse0000.121</td>
</tr>
<tr>
<td>6</td>
<td>wuse0000.152</td>
</tr>
<tr>
<td>7</td>
<td>wuse0000.182</td>
</tr>
<tr>
<td>8</td>
<td>wuse0000.213</td>
</tr>
<tr>
<td>9</td>
<td>wuse0000.244</td>
</tr>
<tr>
<td>10</td>
<td>wuse0000.274</td>
</tr>
<tr>
<td>11</td>
<td>wuse0000.305</td>
</tr>
<tr>
<td>12</td>
<td>wuse0000.335</td>
</tr>
</tbody>
</table>

To assign each day of simulation the right map a lookup table (WUseofDay.txt) is necessary:

| <,0.5> | 335 |
| [0.5,32> | 1 |
| [32,60> | 32 |
| [60,91> | 60 |
| [91,121> | 91 |
| [121,152> | 121 |
| [152,182> | 152 |
| [182,213> | 182 |
| [213,244> | 213 |
| [244,274> | 244 |
| [274,305> | 274 |
| [305,335> | 305 |
| [335,> | 335 |
Preparation of settings file

All input and output files need to be defined in the settings file. If you are using a default LISFLOOD settings template, all file definitions are already defined in the 'lfbinding' element.

```xml
<textvar name="PathWaterUse" value="./wateruse">
  Water use maps path
</textvar>

<textvar name="PrefixWaterUse" value="wuse">
  prefix water use maps
</textvar>

<group>
  <comment>
  ************************************************************
  INPUT WATER USE MAPS AND PARAMETERS
  ************************************************************
  </comment>

  <textvar name="WaterUseMaps" value="$(PathOut)/wuse">
  Reported water use [cu m/s], depending on the availability of discharge
  </textvar>

  <textvar name="WaterUseTS" value="$(PathOut)/wateruseUps.tss">
  Time series of upstream water use at gauging stations
  </textvar>

  <textvar name="StepsWaterUseTS" value="$(PathOut)/stepsWaterUse.tss">
  Number of loops needed for water use routine
  </textvar>

  <textvar name="maxNoWateruse" value="5">
  maximum number of loops for calculating the use of water
  = distance water is taken for water consumption
  </textvar>

  <textvar name="WUsePercRemain" value="0.2">
  percentage of water which remains in the channel
  e.g. 0.2 -> 20 percent of discharge is not taken out
  </textvar>

  <textvar name="WaterRegion" value="$(PathMaps)/waterregion.map">
  Water region to restrict water use from taking water of an other
  water region downstream
  </textvar>
</group>
```
PathWaterUse is the path to the map stack of water use

PrefixWaterUse is the prefix of the water use maps

WaterUseMaps is the path and prefix of the reported water use \([m^3/s]\) as a result of demand and availability

WaterUseTS are time series of upstream water use \([m^3/s]\) at gauging stations

StepsWaterUseTS is the number of loops needed for water use \([-]\)

maxNoWateruse is maximum number of loops for calculating the use of water (distance water is taken for water consumption)

WUsePercRemain is the percentage of water which remains in the channel (e.g. 0.2 -> 20 percent of discharge is not taken out)

WaterRegion (optional) is a map with nominal water regions in order to restrict water use from taking water of another water region downstream.

Finally, you have to tell LISFLOOD that you want to simulate water use. To do this, add the following statement to the 'foptions' element:

\[
<\text{setoption name="wateruse" choice="1"} />\]

### Using a water region map

Setting the option:

\[
<\text{setoption name="useWaterregion" choice="1"} />\]

The water use function is restricted only to a water region. No water is taken from downstream of a water region. In order to use this option you have to provide a waterregion.map in the map folder.

### Water use output files

The water use routine can produce 2 additional time series and one map (or stack), as listed in the following table:

<table>
<thead>
<tr>
<th>Maps</th>
<th>Default name</th>
<th>Option</th>
<th>Units</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>WaterUseMaps</td>
<td>wusexxxx.xxx</td>
<td>repwateruseMaps</td>
<td>(m^3/s)</td>
<td></td>
</tr>
<tr>
<td>Time series</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Number of loops</td>
<td>stepsWaterUse.tss</td>
<td></td>
<td>(-)</td>
<td></td>
</tr>
<tr>
<td>WaterUseTS</td>
<td>wateruseUps.tss</td>
<td>repwateruseTS</td>
<td>(m^3/s)</td>
<td></td>
</tr>
</tbody>
</table>
Annex 9: Simulation and reporting of water levels

**Introduction**

Within LISFLOOD it is possible to simulate and report water levels in the channel. The simulation of water levels is *optional*, and it can be activated by adding the following line to the 'lfoptions' element:

```xml
<setoption name="simulateWaterLevels" choice="1" />
```

If the option is switched on, water levels are calculated for channel pixels where either kinematic or dynamic wave routing is used. Using this option does *not* influence the actual model results in any way, and it is included only to allow the model user to report water levels. The actual *reporting* of the simulated water levels (as time series or maps) can be activated using two separate options.

**Calculation of water levels**

For channel stretches that are simulated using the dynamic wave, the water level in the channel is simply the difference between the channel head and the channel bottom level. For kinematic wave stretches, only approximate water levels can be estimated from the cross-sectional (wetted) channel area, $A_{ch}$ for each time step. Since the channel cross-section is described as a trapezoid, water levels follow directly from $A_{ch}$, channel bottom width, side slope and bankfull level. If $A_{ch}$ exceeds the bankfull cross-sectional area ($A_{bf}$), the surplus is distributed evenly over the (rectangular) floodplain, and the depth of water on the floodplain is added to the (bankfull) channel depth. Figure A9.1 below further illustrates the cross-section geometry. All water levels are relative to channel bottom level ($z_{bot}$ in the Figure).

**Figure A9.1** Geometry of channel cross-section in kinematic wave routing. $W_b$: channel bottom width; $W_u$: channel upper width; $z_{bot}$: channel bottom level; $z_{fp}$: floodplain bottom level; $s$: channel side slope; $W_{fp}$: floodplain width; $A_{bf}$: channel cross-sectional area at bankfull; $A_{fp}$: floodplain cross-sectional area; $D_{bf}$: bankfull channel depth, $D_{fp}$: depth of water on the floodplain.
In order to calculate water levels, LISFLOOD needs a map with the width of the floodplain in [m], which is defined by ‘lfbinding’ variable \textit{FloodPlainWidth} (the default name of this map is \textit{chanfpln.map}).

\textbf{Reporting of water levels}

Water levels can be reported as time series (at the gauge locations that are also used for reporting discharge), or as maps.

To generate a time series, add the following line to the ‘lfoptions’ element of your settings file:

\begin{verbatim}
<setoption name="repWaterLevelTs" choice="1" />
\end{verbatim}

For maps, use the following line instead:

\begin{verbatim}
<setoption name="repWaterLevelMaps" choice="1" />
\end{verbatim}

In either case, the reporting options should be used \textit{in addition} to the ‘simulateWaterLevels’ option. If you do not include the ‘simulateWaterLevels’ option, there will be nothing to report and LISFLOOD will exit with an error message.

\textbf{Preparation of settings file}

The naming of the reported water level time series and maps is defined in the settings file. If you are using a default LISFLOOD settings template, all file definitions are already defined in the ‘lfbinding’ element.

\textbf{Time series:}

\begin{verbatim}
<textvar name="WaterLevelTS" value="$(PathOut)/waterLevel.tss">
  <comment>
    Reported water level [m]
  </comment>
</textvar>
\end{verbatim}

\textbf{Map stack:}

\begin{verbatim}
<textvar name="WaterLevelMaps" value="$(PathOut)/wl">
  <comment>
    Reported water level [m]
  </comment>
</textvar>
\end{verbatim}
Introduction

Soil Water Potential:
The movement of water in soils, its uptake in plants, evaporation, capillary rise, drainage through the soil are all energy related phenomenon. If water is to be removed from a moist soil, work has to be done against adsorptive forces and the more strongly water is held in the soil the greater is the energy required.

pF:
The required energy is measured in terms of the height of a column of water to produce necessary suction or pressure difference at a particular soil moisture level. The pF, therefore, represents the logarithm of the height of water column (cm) to give the necessary suction.

LISFLOOD offers the possibility to calculate pF values from the moisture content of both soil layers. The calculation of pF values is optional, and it can be activated by adding the following line to the 'lfoptions' element:

```xml
<setoption name="simulatePF" choice="1" />
```

Using this option does not influence the actual model results in any way, and it is included only to allow the model user to report pF time series or maps. The actual reporting of the computed pF values (as time series or maps) can be activated using separate options (which are discussed further on).

Calculation of pF

A soil’s pF is calculated as the logarithm of the capillary suction head, $h$:

$$pF = \log_{10}(h)$$

with $h$ in [cm] (positive upwards). Values of pF are typically within the range 1.0 (very wet) to 5.0 (very dry). The relationship between soil moisture status and capillary suction head is described by the Van Genuchten equation (here again re-written in terms of mm water slice, instead of volume fractions):

$$h = \frac{1}{\alpha} \left[ \left( \frac{w_s - w_r}{w - w_r} \right)^{1/m} - 1 \right]^{1/n}$$

where $h$ is the suction head [cm], and $w$, $w_r$ and $w_s$ are the actual, residual and maximum amounts of moisture in the soil respectively (all in [mm]). Parameter $\alpha$ is related to soil texture. Parameters $m$ and $n$ are calculated from the pore-size index, $\lambda$ (which is related to soil texture as well):
\[ m = \frac{\lambda}{\lambda + 1} \]
\[ n = \lambda + 1 \]

If the soil contains no moisture at all \((w=0)\), \(h\) is set to a fixed (arbitrary) value of \(1\times10^7\) cm.

**Reporting of pF**

pF can be reported as time series (at the locations defined on the “sites” map or as average values upstream each gauge location), or as maps. To generate time series at the “sites”, add the following line to the ‘lfoptions’ element of your settings file:

<setoption name="repPFTs" choice="1" />

For maps, use the following lines instead (for the upper and lower soil layer, respectively):

<setoption name="repPF1Maps" choice="1" />
<setoption name="repPF2Maps" choice="1" />

In either case, the reporting options should be used *in addition* to the ‘simulatePF’ option. If you do not include the ‘simulatePF’ option, there will be nothing to report and LISFLOOD will exit with an error message.

**Preparation of settings file**

The naming of the reported time series and maps is defined in the settings file. Tables A7.1 and A7.2 list the settings variables default output names. If you are using a default LISFLOOD settings template, all file definitions are already defined in the ‘lfbinding’ element.

**Time series:**

```xml
<comment>
PF TIMESERIES, VALUES AT SITES
</comment>

<textvar name="PF1TS" value="$(PathOut)/pFTop.tss">
<comment>
Reported pF upper soil layer [-]
</comment>
</textvar>

Annex 11: LISFLOOD options

As explained in Chapter 5, the ‘lfoptions’ element gives you additional control over what LISFLOOD is doing. Using options it is possible to switch certain parts of the model on or off. This way you can tell the model exactly which output files are reported and which ones aren’t. Also, they can be used to activate a number of additional model features, such as the simulation of reservoirs and inflow hydrographs.

The table below lists all currently implemented options and their corresponding defaults. All currently implemented options are switches (1= on, 0=off). You can set as many options as you want (or none at all). Table 10.1 lists all currently implemented options. Note that each option generally requires additional items in the settings file. For instance, using the inflow hydrograph option requires an input map and time series, which have to be specified in the settings file. If you want to report discharge maps at each time step, you will first have to specify under which name they will be written. The template settings file that is provided with LISFLOOD always contains file definitions for all optional output maps and time series. The use of the output options is described in detail in Chapter 8.

For the use of:
- Reservoirs, polders, lakes (Annex 1-3)
- Inflow hydrographs (Annex 4)
- Double kinematic wave (Annex 5)
- Dynamic wave (Annex 6)
- Transmission loss (Annex 7)
- Water use (Annex 8)
- Simulation and reporting of water levels (Annex 9)
- Simulation and reporting of soil moisture potential (Annex 10)

Please find the necessary options in the annex

---

11 Actually, the –listoptions switch will show you a couple of options that are not listed in Table 6.1. These are either debugging options (which are irrelevant to the model user) or experimental features that may not be completely finalised (and thus remain undocumented here until they are)
### Table A11.1 LISFLOOD options (continued on next page)

#### SIMULATION OPTIONS

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>gridSizeUserDefined</td>
<td>Get grid size attributes (length, area) from user-defined maps (instead of using map location attributes directly)</td>
<td>0</td>
</tr>
<tr>
<td>simulateReservoirs</td>
<td>Simulate retention and hydropower reservoirs (kin. wave only)</td>
<td>0</td>
</tr>
<tr>
<td>simulateLakes</td>
<td>Simulate unregulated lakes (kin. wave only)</td>
<td>0</td>
</tr>
<tr>
<td>simulatePolders</td>
<td>Simulate flood protection polders (dyn. wave only)</td>
<td>0</td>
</tr>
<tr>
<td>inflow</td>
<td>Use inflow hydrographs</td>
<td>0</td>
</tr>
<tr>
<td>dynamicWave</td>
<td>Perform dynamic wave channel routing</td>
<td>0</td>
</tr>
<tr>
<td>simulateWaterLevels</td>
<td>Simulate water levels in channel</td>
<td>0</td>
</tr>
<tr>
<td>TransLoss</td>
<td>Simulate transmission loss</td>

</tbody>
</table>

#### OUTPUT, MAPS, STATE VARIABLES

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>repDSLRMaps</td>
<td>Report maps of days since last rain (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repFrostIndexMaps</td>
<td>Report maps of frost index (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repWaterDepthMaps</td>
<td>Report maps of depth of water layer on soil surface (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repSnowCoverMaps</td>
<td>Report maps of snow cover (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repCumInterceptionMaps</td>
<td>Report maps of interception storage (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repTheta1Maps</td>
<td>Report maps of soil moisture layer 1 (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repTheta2Maps</td>
<td>Report maps of soil moisture layer 2 (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repUZMaps</td>
<td>Report maps of upper zone storage (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repLZMaps</td>
<td>Report maps of lower zone storage (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repChanCrossSectionMaps</td>
<td>Report maps of channel cross-sectional area (for each time step)</td>
<td>0</td>
</tr>
</tbody>
</table>

#### OUTPUT, MAPS, METEOROLOGICAL FORCING VARIABLES

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>repPrecipitationMaps</td>
<td>Report maps of precipitation (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repTavgMaps</td>
<td>Report maps of average temperature (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repETRefMaps</td>
<td>Report maps of potential reference evapotranspiration (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repESRefMaps</td>
<td>Report maps of potential soil evaporation (for each time step)</td>
<td>0</td>
</tr>
<tr>
<td>repEWRefMaps</td>
<td>Report maps of potential open water evaporation (for each time step)</td>
<td>0</td>
</tr>
</tbody>
</table>

---

13. This option can only be used in combination with the 'simulateWaterLevels' option!
14. Deprecated; this feature may not be supported in forthcoming LISFLOOD releases. Use `repStateMaps` instead, which gives you the same maps with the added possibility to report them for any required time step(s).
<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>repRainMaps</td>
<td>Report maps of rain (excluding snow!) (for each time step)</td>
<td>0</td>

</tbody>
</table>

### Tables

In the previous version of LISFLOOD a number of model parameters are read through tables that are linked to the classes on the land use and soil (texture) maps. Those tables are replaced by maps (e.g. soil hydraulic property maps) in order to include the sub-grid variability of each parameter. Therefore only one default table is used in the standard LISFLOOD setting.

The following table gives an overview of the main model tables. Please find the tables for any additional feature in annex 1-10.

#### Table A12.3 LISFLOOD input tables

Annex 13: LISFLOOD output

For the use of:

- Reservoirs, polders, lakes (Annex 1-3)
- Inflow hydrographs (Annex 4)
- Double kinematic wave (Annex 5)
- Dynamic wave (Annex 6)
- Transmission loss (Annex 7)
- Water use (Annex 8)
- Simulation and reporting of soil moisture potential (Annex 10)

Please find the list of output maps and time series in the annex.

Abstract

The revised LISFLOOD User Manual documents the LISFLOOD water balance and flood simulation model. The first part of this document gives a detailed description of the characteristics of the LISFLOOD model, focusing on process descriptions and the governing equations. The second part covers all practical LISFLOOD issues, such as installing the model, setting up the necessary input data and running it.
As the Commission’s in-house science service, the Joint Research Centre’s mission is to provide EU policies with independent, evidence-based scientific and technical support throughout the whole policy cycle.

Working in close cooperation with policy Directorates-General, the JRC addresses key societal challenges while stimulating innovation through developing new standards, methods and tools, and sharing and transferring its know-how to the Member States and international community.

Key policy areas include: environment and climate change; energy and transport; agriculture and food security; health and consumer protection; information society and digital agenda; safety and security including nuclear; all supported through a cross-cutting and multi-disciplinary approach.
